INTRODUCTORY

LECTURE.

LABOUR and patience, and an ardent devotion of the whole mind to the object of its pursuit, are the essential properties of those who successfully attempt either to learn or to improve a science. When we enter, therefore, upon the study or investigation of any particular branch of knowledge, it should be our first care to

examine whether we possess the properties I have mentioned, and to discover the peculiar dangers to which we may be exposed, of having them either diminished, or misapplied, or subdued, in our intended progress. If we adopt this mode of preparation in the present instance, we shall certainly discover, that the most common sources of difficulty, of seduction, and waste of power, in every other track of philosophy, will infest and obstruct the path of the electrician.

Wherever Nature urges

man to advance, while his reason is yet feeble, she has kindly ordered the force of passion to assist and to propel. —From the tendencies of this force, proceed our dangers. In its brutal blindness, it is apt to stumble upon errors; and in its readiness to be impressed and interested by first appearances, it is ever exposed to the struggles of obstinacy, and the conflicts of selfishness; and in either of these cases, the toil that overcomes is arduous and slow in its progress, and the necessary patience of thought takes place only

when much time and much labour have been squandered.

Electricity is in its infantine state. Its language is imperfect and obscure. Its appearances are most frequently displayed to amuse the senses, or to astonish the ignorant. The empiric or the itinerant only obtrude it upon the eyes of the world, and it is known by philosophers only as a curious detail of facts, insulated by very peculiar properties, and confused, owing to a want of arrangement or reference to

general principles. In short, electricity is considered as destitute of all stimulants, either to provoke our vanity, or to inflame our ambition. For this reason, it is rarely made an object of eager and complete attention, or of that persevering activity by which alone it can rise to its proper consequence and maturity.

It is to be regretted, that in rearing our minds towards perfection, we should ever regard any motives but such as are purely rational.

The clear eye of Reason views all parts of nature with equal interest, and inspires us with the same plenitude of enthusiasm, whatever object we may follow in the immensity of surrounding wonders. In case you were thus intellectual, every effort to keep your passions from obtruding upon your assiduity would be unnecessary, and introducing philosophy to you, as philosophers, we should lay aside all previous advice and recommendation.—But allowing that you must be impassioned before you are properly industrious, and patient

and persevering, I would wish to convince you that those peculiarities of electricity, which have hitherto depressed and chilled the ardour of enquiry, ought rationally to have a contrary effect.

Is not the vanity of excelling more likely to be gratified where the names of your predecessors are few and obscure, than amongst those who have been selected by public applause from the bright catalogues of improving centuries? Must not the pride of new discoverers enjoy more ample and more

frequent opportunities where the treasures of nature are unexplored, than amongst objects which have been ransacked by the industry and emulation of successive ages? How many years must you toil before you have traced out the steps already impressed by the great Newton? How little the probability of flushing up in the field, he has ranged through, one object which escaped his penetration? and how much less the probability, that its magnitude, when brought forward, will divert that attention which is already fixed

by the accumulation of his stupendous discoveries? In short, if you are impelled by the desires of *animal* nature, you will certainly rush into the course that is the least known; and the ardour of your pursuit will not only be directed, but increased, by the obscurity of its object.

Let me, however, hope that your resolutions are already determined to seek no pleasure from philosophy, but those of the mind; to obey no motive, but that which is rational; and to indulge no views, but those

of enlightening the world by the improvement of your own faculties.

If this be the case, you will find that electricity is most amply invested with *powers* to answer all the great purposes to which you may aspire. It possesses every property which can make knowledge interesting to the human mind. The power, whose laws, whose relations, and whose effects it investigates, is already proved to be one of the most extensive in nature. There is scarcely any science, whose light may not

be increased by it. Many are the arts in social life to which it will communicate new powers, and many are the mysterious circumstances in the history of nature and mankind which it developes, and clearly explains. But to impress you with proper ideas of these advantages, let us amplify on each separately.

1st, We have already discovered the electric fluid to be the cause of thunder, meteors, the northern lights, and of many other appearances in the atmosphere. We

cannot suppose (without a total disregard to the common proceedings of nature) that a power, producing such great effects, should not extend to other objects without number, of equal importance in the general system.

When that influence, by which a stone falls to the ground, was followed to the extent of its connexion with all the phenomena of the tides, the complicated motions of the moon, and the remote circumvolutions of the several planets, if our progress had *then* terminated, our knowledge

of the gravitating power must have been confined and partial indeed, compared with that which still remained to be unfolded; an infinite distance would have removed us from the height whence our present surveys are taken; we should never have reached that extreme point where its sway decides the return of two hundred vast worlds, which, with a velocity that mocks our comprehension, had fled from our neighbouring skies, in one direction, for three hundred successive years. We should never have penetrated the mass of

this world, and the surrounding planets, so as to measure their varying attractions and solidities; nor should we have seen the stupendous sun in its greatest glories, as a central world, surpassing in bulk and consequence a million of such as we inhabit; — much less should we have surveyed the surrounding universe as a plenitude of systems, each of whose component parts are formed of all that is great in the united mass of our sun and its attendant worlds, and yet these parts are more numerous than the drops that form the vast Atlantic.

In short, *wherever* we stopped in our pursuit of the gravitating influence, by ascending, for thousands of years, from one combination of wonders to another, *there* we should have found ourselves on the entrance only of its boundless activity. But the power of gravity and the electric fluid are alike the agents of the same wise Omnipotence, and we may rest assured that their characters are similar, and that our first enquiries, however successful in the display of their great operations, afford but faint, and confined and partial views

of what future investigation may unfold before the eyes of philosophy.

2dly, I have observed that the light of other sciences may be increased or brightened by that of electricity. Its present connexion with some of them is merely that of conjecture and extravagance. In astronomy, it has been employed to account for the tails of comets; and the motions of these bodies have been ignorantly supposed incapable of explanation, without recourse to its agency. In navigation, it

was expected to have worked great marvels, by furnishing a magnet that would turn towards the Pole, without any variation. But, alas! this imaginary attainment appeared and vanished with equal rapidity.

It is rather extraordinary that the electric fluid has not yet been thought of as capable of any connexion with mechanics. In a science, the object of whose skill is the commencement, the increase, and the management of force, it is surely reasonable to expect that a power may be

highly advantageous, which acts with unparalleled velocity, and which overcomes the most obstinate resistance.

Should some genius hereafter discover the method of employing Berthollet's new gun-powder with safety, perhaps this improvement in gunnery may owe its success to the possibility of firing the dangerous ingredient, at a great distance, by the aid of the electric fluid.

Much has been attempted and professed by electrical empirics, in the art of medicine;

but hitherto electricity has been chiefly employed as the instrument of quackery and imposture. A few scientific professors have tried its influence where the idea of doing no harm, and the despair of doing much good, has disposed them to try any thing. There are certainly some striking cases, in which it has, seemingly, removed the most obstinate obstructions. But that skill is unknown, which is to develope its influence on the various parts of our organization, or which can answer for its effects in specific cases, so as to render the ap-

plication of it either safe or prudent.

In chemistry, much has been done by its union with electricity; but much more may be rationally expected. The properties of all fluids and solids are found to have been changed, when previously exposed to the action of the electric fluid. It separates the component parts of those substances on which the strongest fire of a reverberatory has no effect, and it is capable of being applied with accuracy and ease, where no other cause of change is ap-

plicable. In this connexion, however, our greatest desiderata are certain improvements in our apparatus. What we have, is complicate and troublesome, and adapted to very few purposes, and a great deal of invention must become active before the possible rapidity of our progress can take place. In these Lectures I shall present you with several instruments, which have been employed by myself for this purpose; and I shall endeavour to place your minds in such a train of thought as may lead you to the discovery of others, much

more commodious when used,
and much more extensive in
their application.

Not more stimulating to
the ardour of pursuit, is the
prospect opened by the con-
nexion of chemistry with elec-
tricity, than that of the same
science with natural history.
By the light emitted from this
collision, we have already
explained one of the most
extraordinary appearances in
the animal system. The tor-
pedo and gymnotus have been
discovered to arrest their prey
at a distance, to benumb the
most powerful energies of

life, and instantaneously to inflict death upon creatures far surpassing themselves in strength and velocity; by collecting the force of thunder, with a frequency adequate to their own wants; by darting it in all the directions in which escape is tried by the consternation of their prey; and, finally, by residing in a medium, to every part of which the fire and fury of their lightning is commanded forth at pleasure.

Provided Signor Galvani be right, the knowledge of

the electric fluid is leading us rapidly into a full investigation of the nervous influence, and of all the mysteries connected with the sensations and motions of animal life.

To the previous advantages, derived from the union of electricity and natural history, several theorists have added the discoveries which are to proceed from the influence of the electric fluid on the growth and nourishment of vegetables. No decisive experiments have yet proved that such an influence

can take place. The fact is positively asserted by some, and is as positively denied by others. I shall hope to give you an account of what has been done on the subject. Indeed, I am rather disposed to expect that the activity of the electric fluid may yet be very beneficial in this part of natural history.

The power it possesses, of dilating every circulating vessel, of irritating whatever is capable of irritability, and of accelerating the motion of animal and vegetable juices in the minutest channels, af-

fords a strong presumption that it may hasten, not only the growth of plants, but add much to their size, and produce several extraordinary changes in their internal properties and their external appearance. There are several desiderata which delay our progress in this business. We have not discovered an easy and cheap method of keeping up a constant current of the electric fluid; nor do we know how to convey it in a sufficient abundance thro' all the parts of the same plant at the same instant of time.

3dly, Any agent, which alarms the senses by a rare and anomalous display of its operations in the visible system of nature, is to man, while groping in the night of ignorance, a most formidable tyrant. Horrors attend its appearance, and the general fear it calls forth is pregnant with calamities of long permanence, and of tremendous magnitude and extent. The hour of its sway, is that of torture to millions, and, in the succeeding hours of timidity and depression, new powers come into action, far more terrible

and destructive than itself. The general mass of ignorance is, each time of its appearance, enlarged and condensed, and the reign of superstition is confirmed and darkened. It arms the ruling priesthood with the dagger; it clothes them with bloody robes, and gluts them, hungry in their demands of sacrifice, for the angry god whom they represent, with the first-born of every kind.

The terrors, under which it subjects the quaking multitude, are equally merciless to the flocks of the field, and

to the most helpless of human innocents. It arms whole legions of tyrants, which tyrants collect hordes of voracious janissaries, who unite in one confederacy to plunder, to enslave, to corrupt, and, finally, to exterminate those whom they at first frightened and deceived.

In all ages the thunder of heaven, by the display of its own peculiar greatness, and by co-operating with other awful agents in nature, has contributed most powerfully to promote the cause of imposture and tyranny. The

roar, by which it shakes earth and sky; the blaze, which it spreads in one instant thro' the whole concavity of heaven; the impetuosity with which it precipitates palaces, castles and temples into ruins; the impotence of the mightiest amongst visible beings, when assailed by its fury: these tremendous consequences of its own immediate agency are accompanied by others, resulting from that agitation of elements which it has produced. It inundates the earth with a deluge. It lets loose the tempestuous storm from the black cloud in which it

is supposed to reside; and the concussions of earthquakes and volcanos, are frequently amongst its attendant horrors.

All the preceding are circumstances whose powers are fully adequate to the prostration of every ignorant mind, at the feet of blasphemous fraud and usurpation. We consequently find, that the supreme god of the Greeks was the god of thunder, and that their descendants secured the obedience of plebeians and slaves, by cherishing the same superstition, and by con-

triving new rules and ceremonies, new cruelties and absurdities, to renovate the general panic, whenever awakened by the recent devastations of a thunder-storm.

By the science of electricity, however, the future possibility may be exterminated, of renewing these frauds or blaspheming the benevolence of nature, by perverting the sublime language of its operations to the purposes of human wickedness and the promotion of human misery. It has enabled the most common artificer to avert every

danger attending a thunderstorm, and consequently to silence every apprehension. It teaches the vulgar mind to smile at a thousand religious ceremonies, before the reverence of whose age, and the dignity of whose priests, the ostentation of modern hierarchies dwindles into meanness and mummery.

When the domes or spires of our most sacred temples are cracked by lightning, instead of trembling before an angry God, and invoking his presumptuous servants to light his altars, and massacre

his creatures, we have only to lament that the blacksmith had not been employed, and that his iron rods were not erected. If thick clouds are gathered together in the west, and, amidst the noon of day, bring on the darkness of night, the approaching appearance is surveyed as the probable source of amusement, and the philosopher, awakened from contemplation into business by the sound of his bell, conducts the lightning into his habitation, or commands it to any distance prescribed by his own pleasure and convenience.

If you were to extend the preceding comparison of the present and past state of man, in its relation to one of the grandest agents in nature; if you were still further to investigate the important changes which have resulted from the discoveries of electricity, you would, I think, look up to it as entitled to the highest estimation of philosophers:—would you not likewise acknowledge that no tyrannical hero had ever proved more beneficial to his species, than that republican, who, when he had disarmed the clouds of their fury, armed his coun-

trymen on the very same spot
in the cause of freedom and
humanity ?

On the banks of the Dirce,
Greece, in her most civilized
hour,—Greece, displaying to
the wondering world a con-
stellation of the most splendid
luminaries that ever adorned
and enlightened the human
species, celebrated with hymns
and dances the birth of that
benefactor, who first pressed
the grape, fermented its juice,
and poured its joys into the
bosom of man.

When the golden times

come, in which posterity will look back to the age of tyrants, of their priests, and the whole host of their janissaries, as the dark and barbarous age of mankind struggling with monsters and wild beasts, will not the higher orders of beings, whose intellects brighten the glorious day in which they live, express a gratitude similar to what I mentioned, on the banks of the Delaware?—Let poetry be raised to what it was in Athens, the perfection of philosophy. Let every art reach the fullest maturity which reason can give it,

when cultivated by the leisure and education of myriads improving thro' successive centuries; and amongst the highest objects of its praise, will not eminence belong to the example and intellectual greatness of Benjamin Franklin, who, when he had wrenched the thunderbolt from the grasp of tyranny and fraud, enrolled himself amongst the heroes and patriots of his country, chased away the minions and mercenaries of oppression, and amongst the ruins accumulated by despotism in the fury of its dying hour,

established the first free community that ever blest the eyes of men?

I have been amplifying, gentlemen, on the *obvious* utility of that science, which it is your object soon to acquire; but I will repeat my wishes that the pure and elevated condition of your minds may render all such amplification unnecessary.—He that enters the path of knowledge, as he would that of commerce, or who begins his enterprize with specifying the benefits he is to secure, will never make any considerable progress. He will

soon be arrested by disappointment, and will terminate a labour which does not provide him with what he particularly expected.

There is but one consideration that bears sway in the soul of a philosopher. That truth stands alone which interests his desires, and stimulates his active principles. He is convinced, that to follow nature is to follow the sure road to boundless attainments: for its treasures fill the universe; its means of gratification are not less various than those scenes and

objects by which it has diversified, enriched, and adorned immensity; and the wonders, by which it elevates the mind, and overwhelms it with transport, succeed each other in multitudinous combinations, not less numerous than the swarms of life in summer, nor less rapidly than the instants which form eternity. Nay, the paradise of a philosopher, devoted to the study of nature, is not confined to earth, or sea, or air; to the third or fourth heavens; but includes those distant regions which the light of a day, that shone thousands of years

ago, has not yet reached ! He feels it every where ; he enjoys it at all times. Its pleasures burst forth from every visible object ; they spring from the ground he treads upon. The atmosphere teems with them. They are to be found in the mass and in the lowest depths of the ocean. They flourish in the desert and amongst precipices and rocks. They are present amongst the horrors of volcanos and earthquakes ; nor do they forsake the mind when looking forward to the destruction of worlds and their systems.

But in case the philosopher wanted those powers of beatific vision which I have described; allowing that a cloud separated him from those views of the universe, by which science ravishes and enraptures the mind; allowing that all discovery had hitherto eluded his pursuit, and that his labours opened no other prospect but that of aiding future attempts; he has still to pride himself in the attainment of a most glorious reward.

Mental pursuit is a discipline that not only increases

the strength we have, but creates new and greater energies in man. The faculties of the soul, like those of the body, become gigantic and mighty, by exertion only: and what delicious consciousness equals that of a mind triumphing in its own vigour? satisfied with its own exertions, and fitted for those more important circumstances of action which may still remain for it?

But does the science, upon which we are entering, participate in that character of philosophy, whose improving

powers I have just described? When I answer in the affirmative, I feel that I shall be justified by your future experience.

Electricity possesses much of what is admirably adapted to discipline the mind. Its new principles, though few, will admit of extensive application; but that application will belong to those only who can proceed patiently through a great deal of intricacy and embarrassment. The appearances of electricity, likewise, are entangled with the effects of many dis-

tinēt causes. They require, therefore, much of that toil which separates carefully, which combines judiciously, which selects with severity, and then arranges with clearness and precision. Besides, this science demands the co-operation of the hands and the head, or the exercise of manual skill, united with a ready capacity of inventing and diversifying the means of experience. The accumulation of electrical facts, moreover, is increasing daily, and consequently affords opportunities favourable to the retentive faculties of the

mind. The circumstances of its experiments are connected by no general system. They are, as it were, insulated; and of course the remembrance of each minute difference requires a distinct exertion, and renders it very difficult to obtain such a familiarity of acquaintance with the whole catalogue of its appearances as will enable you pertinently to bring them forward, either in evidence or explanation.

In short, the science of electricity is well formed for strengthening the memory,

for invigorating its powers of association, and for habituating us to such deliberate and multiplied pains as are necessary to complete the images or mental impressions which, with equal pains, we have previously estimated and selected.

Let your resolutions then be formed to study electricity as a science in all its tendencies, favourable to the general interest of knowledge, and to your own particular improvement; devote to it a portion of your most undivided attention; make it a

work of labour and patience, and if disappointment or fatigue should subdue you, determine either to reject it altogether, or to pursue it with ardour, with perseverance, and all the best energies of your several faculties.

The directions which are appropriated to the study of electricity, as a distinct branch of science, are of two kinds.

1st, There are directions which have a reference to your progress, while you receive the instructions of your tutor.

2dly, There are other directions by which you will be guided in your future endeavours to increase the store of known facts, or to develop the unknown laws and principles of electricity.

1st, While you attend the present course of Lectures, endeavour to keep your eyes and your memories altogether unencumbered, so that you may perceive the order in which the several parts of the apparatus are united: you will thus be able to retrace with new force of impression, and at the same time to cor-

rect those ideas which I shall have previously endeavoured to communicate by verbal description.

My plan of instructing is formed with a view to aid you in this method of improving yourselves. I begin with describing the simplest machinery, and the appearances immediately dependant on their operation. I proceed gradually with small additions to the machinery already described, and with the facts resulting from each separate addition. After I have first described, I make

the experiments, so that each successive appearance may answer to the order observed previously in the verbal description. In consequence of this method, the memory is aided by repetition, and what it has received by the ear, is rendered more permanent by the subsequent impressi^on of what is offered to the eye.

A most detrimental custom belongs, I observe, to some pupils. They spend their whole time in looking at their papers, and in scribbling imperfectly, what they as imperfectly recollect of the lec-

turer's expressions. Their business consequently becomes so very complicate, that to instruct them with any accuracy, or to any extent, is altogether impossible. At one and the same instant, they have to write, to see, to make up the expressions they remember imperfectly, and to dispose of what is unintelligible in the tutor's language, who, lecturing extempore, if he does it properly, must be now and then at a loss in attempting to change the words and order of his sentences, whenever he finds, from the looks of his pupils,

that they do not comprehend him.

When the lecture is over, then is your most important care to commence. You should, as soon as possible, endeavour to copy upon paper, what you have taken into your memories; for, rest assured, that if you have learned any thing well, you will be able to write it down. A sure evidence that you have learned nothing, is the inability of expressing the ideas which you have received. Besides, from what you write, you will know both the quantity and

the quality of what you have gained ; and the one may be increased, and the other corrected, by having recourse to your tutor, or to those books which are written on the subject of your enquiry, or by endeavouring, on the apparatus, to repeat his experiments, and to recover the circumstances you had forgotten.—In experimental philosophy, however, it is of the utmost importance, that you should attend the same lectures twice ; for by this means, when you retire to examine the stores you have collected, the fruits of your second at-

tention will always mature those of the first.

2dly, Should your love of science gain such strength, during the course of your instruction, that you are determined to pursue it, you will then have new circumstances to regard. It will be necessary that you should provide yourselves with a proper apparatus, and patiently to toil through the whole of that discipline, which is requisite to the formation of a dextrous experimentalist.

In these Lectures I shall

describe, very minutely, the proper instruments of the science. But when you know the best of these, you should likewise know that there are two ways of procuring them. You must either have recourse to those who live by making them, or you must work for yourselves. The former method is expensive, and takes away from electricity one of its most advantageous singularities, that of being cheaply pursued and cultivated. Besides, this method is the slowest possible; for he who makes experiments well, must vary them a thousand dif-

ferent ways; and great is the loss of time and labour, great the waste of power, that must harass those who have first to direct, and then to wait upon the conveniences of a common instrument-maker.

If you should resolve to work for yourselves, few utensils are necessary. The first and most important is a turner's lathe; by which you may furnish yourselves with balls, caps and the pedestals of your stands. Indeed, there is scarcely one diversity of means in electricity, with

which you may not be provided, when you have acquired a moderate share of skill in using this machine.

A blow-pipe is necessary for bending tubes, and for opening and closing such as are of considerable diameter. The art of filing with tolerable truth; of covering wood and glass with tin foil, so as to leave no points, edges, or wrinkles; together with some little dexterity in the inferior employments of chemistry: these arts, I say, in conjunction with that of turning and of blowing glass, comprizes

the whole mechanical knowledge that is wanted by an electrician. In the track of your pursuit, a multitude of unknown necessities must arise: but these, when supplied or conquered, will add to the interest of your employments, and the pleasures of your success.

In the Lectures you are now to hear, you can expect that information only which relates to the most important parts of the science. You may abundantly increase your store of electrical facts, by

directing your future attention to

Dr. Franklin's Letters on Electricity.

Dr. Priestley's History of the Science.

Mr. Cavalio's Treatise, together with his several papers on the subject, to be found in the Philosophical Transactions.

A small pamphlet containing curious particulars relating to positive and negative electricity; by Dr. Milner, of Maidstone, in Kent.

Mr. Brook's "Miscellaneous Experiments," &c.

Mr. Bennet's "New Experiments;" and

Mr. Reed's "Summary View of the Spontaneous Electricity of the Earth and Atmosphere.

There is little in the Philosophical Transactions, which Dr. Priestley has not condensed in his History.

Foreigners attend much more to chemistry than electricity; in their journals, therefore, you will discover nothing to reward the toil of ransacking them, if you except Volta's papers in the "Scelte D'Opuscole."

A

SYLLABUS

OF THE

FOLLOWING LECTURES.

	PAGE
THE general cause of electrical appearances - - -	1
The effects peculiar to the different degrees of its operation - - -	2
Circumstances which affect its operation - - - - -	3 4
Different characters of its effects, or the distinction of positive and negative electricity - - - -	5 6 /
Method of determining them - - -	7 10
The duration of electrical effects	11
The possibility of exciting them in bodies of all dimensions - - -	12
Their extent	
The law of electrical influence -	

Theory to account for the electrical appearances just described		
The corporeal nature of the cause of electricity - -	17	
The necessity of its being subject to an attractive force, and in its turn of its exercising it -	19	
The change of this force, in consequence of the contact of different bodies, adequate to all the appearances dependant on friction	20	26
Facts which seem to confirm the theory	27	30

The only difference between pressure and friction - -	30	32
Immediate application of the theory to the elucidation of described facts	32	35

The appearances dependant upon the collection and motion of the electric fluid, when produced by friction	37	
Apparatus necessary to shew these appearances - -	38	

SYLLABUS.

III.

Page

The sound of the electric spark	40
Those varieties of the spark which depend upon the various forms and dimensions of the body around which the fluid is collected	42
The figure of the spark	48
The length of the spark	51
The force of the spark	60
The light of the spark	63

Appearances attending the accumula- tion of the electric fluid upon glass, and other electrics	67
Description of the requisite apparatus, and a general view of the appearances	67 71
Varieties in the appearances which proceed from the possible varieties of the glass vessel	71
- - - - - of the coating	75
- - of the uncoated part of the glass	77
- - - of the discharging-rod	83
Theoretical view of the preceding facts taken from three leading principles	85 97

1. The corporeal nature of the electric fluid - - - 85 97
 2. The union of the electric fluid with other bodies dependant upon an attractive force - - - 85 97
 3. A certain quantity only of the electric fluid belongs to bodies in given circumstances - - - 85 97
- An application of the preceding principles to the accumulation of the fluid on the surface of electrics, and to its passage thro' conducting bodies 98 102 ✓

The theory applied

- 1st, To the correction of the language used by electricians concerning the different states of the same body 102
- 2d, To the elucidation of the several progressive changes which take place when a body is charged 108
- No necessity for a repulsive power 109
- Dr. Franklin's theory examined 112 116
- 3d, To the appearances of the discharging-rod - 116
- 4th, To those of the metallic coating 118

SYLLABUS.

v

Page

5th, To the analogy between the ap- pearances of charged air, and of other charged electrics -	119
6th, To the breaking of the glass by the charge - - -	123

The ELECTROPHORUS—a descrip- tion of its construction -	147
The method of using it -	148
The effects of the electrophorus	149
Mr. Bewley's explanation	150
Its difference from a common electrical machine - -	153 157
An application of principles already explained, to the illustration of the electrophorus -	157 163

The INSULATED ELECTROPHORUS described - -	163
The various appearances attending the use of it - -	163 174
Explanation of the preceding appear- ances - -	174 181

- 3d, The ease with which the electric fluid is rendered luminous in any particular body, is increased by increasing the rarity of that body 218
- 4th, The brilliancy or splendour of the electric fluid, in its passage through any body, is always increased by lessening the dimensions of that body 223
- 5th, In the appearances of electricity, as well as in those of burning bodies, there are cases in which all the rays of light do not escape; the most refrangible are those which escape first or most easily - 228
- 6th, That the influence of different media on electrical light is analagous to their influence on solar light 230
- Principles which account for the varieties of appearance belonging to the light of electricity :
- 1st, The attractive force which unites the constituent parts of different bodies must be altered by increasing or diminishing the quantity of any particular constituent in the body 238 242

2d, The attractive force, which unites the particles of light to any body, must be diminished, or increased by an addition to its natural share of the electric fluid	-	244
---	---	-----

VOL. II.

On the Conducting Powers of Bodies.

The principle on which the examina- tion of these powers is founded	3	
<i>The necessary apparatus</i>	4	8
Lane's electrometer examined	9	
Necessity of a discharging-rod	10	
Its requisite properties	10	12
Description of the discharging-rod	12	16
Instrument for giving the fluid its choice of two passages	16	19
Instrument for measuring the conducting powers of bodies by the expansion they cause	19	30

	Page
The connexion of the conducting power with the terminations of the bodies which form the electric circuit.	
1st, Varieties of the striking distance, when the charge strikes from one flat surface to another -	31
2d, From one point to another	32 39
3d, From a flat surface to a point	39 41
4th, From balls to points -	42 46
Observations on the preceding facts	47 49
An attempt to account for the varieties of the striking distance, which de- pend on the terminations of conduct- ing bodies - -	49 61

On the conducting power of water.

Additional apparatus for the purpose of determining this power -	62 66
The different resistances made by co- lumns of different dimensions of water - -	67 70

The comparative striking distances when the electric fluid passes <i>luminously</i> through columns of different dimen- sions	-	-	70	72
The conducting power of water deter- mined by its expansion during the passage of the fluid	-		72	74
The same power examined by the resi- dues of charges	-		74	75

LECTURES

ON

ELECTRICITY.

ALL those electrical phenomena, which depend on the operations of art, are the consequence of friction. By rubbing a piece of dry silk, of hair, worsted, leather, or skin, against a surface of glass, of sealing-wax, rosin, amber, or of any one body in a long catalogue of filicious and resinous substances, which might be enu-

merated, a power is communicated to the rubbed surface of attracting such light bodies as the down of feathers, the floating particles of dust, and the threads of linen and silk, if delicately suspended.

If the rubbed surface be equal to that of a few inches only, we may perceive a whizzing, snapping noise, when the finger is applied; the appearance of light, if the affected surface be carried into the dark; and a creeping sensation, if it be applied to the skin.

The operation of rubbing, when attended with the effects which I have now described, is called the *excitation of a body*, and all bodies,

which are capable of this excitation, are called *electrics*.

Many are the peculiarities immediately connected with the act of excitation: these I would now recommend to your attention.

I. If the least moisture or dirt defile the surface of your electric, the degree of excitation will be very much diminished: this cannot be said of grease and other inflammable bodies. The effects of excitation may be increased by oil very moderately used; and you will hereafter see that an amalgam of metals and some fat substances is daily used for the same purpose.

II. Different substances are differently affected by this ope-

ration. The diversity is best explained by a fact.

FIG. I.

AB is a glass stem, not less than six inches in height: Bc is a wooden pedestal, into which the glass is fixed; AD is a wire, to whose blunt termination are annexed two very fine filken threads, e, f, whose length is not less than four inches. If a polished surface of glass, when excited, be brought near the threads, e, f, they will separate into the situation of g and h. But if, when thus circumstanced, you approach them with an excited surface of wax, rosin, unpo-

lished glass, &c. the threads g and h close again into the situation of e, f. Vice versa, If the excited wax or rosin, or unpolished glass, be first applied to the threads, a separation will take place, and the subsequent application of the excited glass will bring them together.

It is of the greatest importance to remember, that every excited surface, which closes the threads, when previously separated by *polished* glass, is said to be *negatively excited*; and that every surface which, on application, produces no effect, or separates them still further, is said to be *positively excited*. Vice versa, If the threads be separated by *excited sealing-*

wax, whatever surface then closes them, is, *charged positively*; and whatever surface separates them wider, or produces no change, is, *charged negatively*.

The ability of determining these different states includes a very great part of its operations in the present state of the science.---- Electricians, therefore, have invented a variety of instruments, from the idea that some of them utter the same language much more expressively and distinctly than others.

In very delicate experiments, one thread has been substituted by electricians, in the place of the two threads, e, f, Fig. I. To

render it susceptible of the least influence, they have used the finest drawn filament which could be gained from the silk, as it immediately proceeded from the worm. This thread, when previously affected by an excited surface in one state, on the application of a surface in a different state, would be instantly attracted. Balls made of the pith of elder have been affixed by several electricians to the extremities of the threads.

But the use of every contrivance of this kind has been wholly superseded by a very late invention, which I shall now describe.

AB, Fig. II. is a piece of brass passing through the neck of the

glass vessel, A, F, C, D. At the extremity of the brass, B, are fastened two strips of gold leaf, m and n. The bottom of the vessel, Pg, has been usually made of some metallic substance; connected with which, is a strip of tin foil, o, p. In the brass ball, A, a hole should be made, so that a plate or any other necessary appendage may be fastened.

The excellence of this instrument consists in the ready separation of the gold leaf strips, on the approach of any excited electric.

The instantaneous motion visible in the strips, on the contact of an evaporating fluid with the ball A, shews the vast superiority of this to all other electroscopes.

I should have observed, that the dimensions of parts in this instrument, are the following. --- It is usually about four inches in diameter, and five inches high. The diameter of the neck should be regulated by the size of the brass wire. The strips are about two inches long, and one-fourth of an inch wide. Some ivory or wood should be screwed upon the extremity, B, or the strips cannot be glued on. The tin foil is usually fixed so high as to be on a level with the lower extremity of the strip. However, I would prefer a vessel of much larger dimensions, so that wider and longer strips might be used, and of course a greater surface exposed to the electrified atmosphere in the ves-

fel; and I would wholly exclude the tin foil and the brass bottom, as having no other effect than that of discharging the atmosphere before it can be examined.

III. The variety of states in excited bodies, which I have just now described, and taught you to distinguish, is not confined to the surface of different bodies. It may be observed in the opposite surfaces of the same body; in different parts of the same fluid, and, in some cases, of the same surface. The opposite sides of excited glass are always *positive* and *negative*.--- At a distance from that portion of the atmosphere, which gives positive signs, may be always found a portion which gives signs the

very reverse : and it has been ascertained that a glass stem, three feet long, when rubbed, will be found, on different parts of its surface, to separate and close the gold leaf strips alternately.

IV. You will observe, that we scarcely know the time in which glass, wax, rosin, &c. lose the powers they acquire by excitation. I have some reasons for believing that a surface of this kind, if kept in air perfectly dry, may be kept, without any new friction, in a state of excitation for years.

V. Bodies of any thickness may be excited. I have some glass cylinders in my possession, of very great density, whose effects have

not proved sensibly less than others, which electricians, reasoning a priori, would have preferred, as being much thicker. I have, likewise, excited glass *stems*, so as to shew equal power with *tubes* of the same diameter.

VI. The sphere of an *excited electric's* influence, or the distance to which it will extend its repellent or attractive effects, as shewn by the gold leaf strips, we may safely say, will depend on the *dimensions* and *goodness* of the excited electric.

The dimensions, however, of this sphere are very much diversified by the different temperatures and humidity of the air. A few floating

particles of dust will cause a variety of result; so will the opening of a door; an increase either of respiration or perspiration in the operator; and, above all, the quantity of flying particles which are perpetually resting themselves on the surface of an excited electric.

Numerous efforts have been made to determine the law of electrical influence. --- Lord Stanhope has proceeded mathematically, and discovered a most accurate agreement between the language of fact and the corrolaries, which he inferred from several abstract propositions. Mr. Morgan, who is well known for his skill in calculation and finance, has furnished us with the

best method of determining this law experimentally.

FIG. III.

A is the convex extremity of an excited surface.

BC is a metallic rod, delicately suspended on the point E.

CF is designed to contain any weight which may be applied to the extremity of the rod.

The apparatus should be as light as possible, and is best made of reed and cork, covered with tin foil.

While the surface, A, is in an excited state, B is brought within

a certain distance of it, and the weight, moved by its influence, is carefully observed. A similar observation is then made at a second, a third, and a fourth distance.

Varieties will be discovered in the result of these observations, proceeding from the impossibility of keeping the surface for any considerable time in the same state of excitation. These varieties, however, are trifling, and, in a vast number of experiments, the weights diminished very nearly in the duplicate ratio of the increased distance,

HITHERTO I have directed your attention wholly to facts.--- We have, therefore, trod on firm ground. I shall now lead you some way into the region of probabilities, and endeavour, by combining the light of conjecture and experience, to give you a more general view of the circumstances which I have represented as the mere effects of friction, or as having no other connexion with each other, than that of being the common attendants of one simple process.

Why the friction of electrics is followed by the consequences I

have just enumerated, is a question immediately suggested by what you have seen and heard: I will now try to answer it.

All electrical appearances must proceed from *something* whose nature is corporeal.

The truth of this proposition is fairly inferred from the dilation of some, and the perforation of most bodies, by the passage of that which is hence called the electric fluid. Indeed, there are facts whose peculiarities at first sight seem to contradict it. Amongst others, is the impossibility of communicating motion to a rod, suspended with the utmost de-

licacy, by conveying the largest attainable quantity of electricity through one of its extremities.---

If (it may be said) a body strikes in this case upon one end of the lever, be its quantity ever so small, with a velocity that is absolutely infinite, why does no degree of momentum take place? It may be answered briefly, that we can produce facts perfectly analogous to the preceding, whose circumstances will not admit of the same doubt.

A cannon-ball, fired through the extremity of a wooden lever, very delicately balanced, will not move it; and this singularity might be adduced with as much justice to

prove that a cannon ball is nothing, as the preceding to prove that the cause of electrical appearances is not a *body*.

But if we admit the corporeal nature of that which is hence with accuracy called the electric fluid, let us attend to the necessary consequences of what we admit :—
1st, That the electric fluid, like all other corporeal substances, is capable of *attracting* and of being *attracted*. 2^{dly}, That in consequence of this capacity, it enters into an union with other bodies, and that as the nature of the substances to which it is united may vary, so the degree of force by

which it is united may shew an equal variety. 3dly, That when the electric fluid is separated from any body, this separation must be the effect of lessening the force by which it was united to that body, and thus giving the attractive force of another body the superiority; or it must be the effect of very much increasing the force of the third body, and thus destroying the equilibrium.

Suppose that any body, A, should be capable of uniting to itself, or suppose the law of its constitution were such as to admit of its attaching fifty particles of the electric fluid to itself, when near or in contact with another body, B, which likewise has an

attraction to those particles; now in case any such change should take place as would add twenty particles to B, and leave thirty only in A, this change, it is evident, must proceed either from a diminution of A's attracting force, or from an adequate increase of force in B.—Having deduced, from the corporeal nature of the electric fluid, such consequences as shew that when it is separated from a body, it must proceed from a diminution of attractive force in the body that yields, or an increase of the same force in the body that takes; let us now examine how friction is likely to be the cause of such changes.

By attending to the nature of friction, we shall find it to be nothing more than a succession of pressure or contacts of the different parts of different substances against each other: and the question in the present case is this;---whether contact is necessarily attended with a change of attractive force in the different substances which are brought together? or whether the close union of a particle of silk, hair, leather, &c. to a particle of glass, may be attended with a change of capacity in those bodies to retain the electric fluid? ---If this question be admitted, I think the particular mode in which friction operates, is easily discovered. I will explain myself by

a reference to what I regard as analogous facts.

Say, that the vitriolic, the nitrous, or marine acids, contain any particular quantity of heat; water likewise contains its due quantity; but when any two of these bodies are united, their capacity for retaining heat is diminished, and consequently, as soon as the mixture is made, a vast quantity of heat is discharged, and absorbed by such surrounding bodies as are ready to receive it.

Again, if salt and water be mixed, a combination is made, whose capacity for retaining heat is increased, and consequently the mixture feels cold, or attracts heat

from any body which may come in contact with it. On those who deny the corporeal nature of heat, the preceding instances will not (I am sensible) have any other effect than to serve as an elucidation. In my opinion, they are actual decompositions, similar to what I am now explaining, in which one constituent body is let loose, because the force which attracted it, is diminished by the union of two other bodies.

But if a particle of acid or water quits another substance, in consequence of proximity or contact to a third substance, why, in like manner, may not a portion of the electric fluid be let loose, owing to the greater or less capacity of

any two bodies when pressed more closely together, than during their separation.

The instances I have now produced, and indeed all other instances derived from a knowledge of chemistry, it may be said, are applicable to fluid bodies only: whereas, when the electric fluid is let loose, the effect proceeds, in most known cases, from uniting the surfaces of two solid bodies.

A moment's consideration must, I think, convince us, that the instances alluded to, differ in *degree* rather than in *nature*.

When fluids are united together, the contact is most complete:

for the particles of the body approach each other in a greater number of directions than when the surfaces of two solids are united. But there is the same contact in both cases, with this difference only, that in solid bodies it takes place between two particles in one point. Briefly, then, my idea of the manner in which friction operates, is this;—when two electrics are pressed closely together, while they *continue* together, they become capable of taking more or retaining less; and if this be allowed, I think the various appearances of bodies in a state of excitation are easily accounted for.

However, it may be asked, If the change produced in the sur-

faces of two bodies be the effect merely of bringing the bodies nearer together, why does not contact alone produce the same effect? I must answer, that the several instances of spontaneous electricity enumerated by Wilcke, Epinuss, and Others, appear to me to be so many evidences of the preceding theory. In those instances we see the excitation of surfaces take place in such circumstances as will not rationally admit of any other cause than simple contact.

I. When sulphur is melted into an earthen vessel, if the vessel be supported by a conducting substance, the sulphur, when cold and separated from the vessel, is strongly electrical.

II. If sulphur be melted into glass vessels, when cold, the glass, whether supported by electrics or not, will be positively electrical, and the sulphur negative.

III. Melting sealing-wax, when poured into glass cups, acquired a negative electricity; upon being separated, the glass was positive.

IV. Melting sealing-wax, when poured into sulphur, became positive, and the sulphur negative.

V. Sulphur was melted into metal cups: while they were together, no signs of electricity were discovered; but as soon as they were separated, strong signs of electricity were discovered: the

cup was negative, the sulphur positive.

It is evident, I think, from the preceding facts, that contact alone is adequate to the production of electricity. I would add, that in the only case where contact may be applied most completely, electricity is produced in a most remarkable degree.---By Bennett's new electroscope, we find that the slightest evaporation (which is certainly the union of watery with aerial particles) produces immediate signs of electricity. How rationally all the electrical appearances of our atmosphere may be ascribed to the same source, will be shewn more fully hereafter.

Before I quit this subject, I would explain to you the reasons why, in many cases, agreeably to the preceding hypothesis, friction is necessarily much more powerful in its effects than pressure.

Suppose A to be a particle of silk, brought into contact with a particle of glass, which I call B; by the increase of attraction consequent upon the union, the combined bodies become capable of attracting a portion of the fluid, which, I say, is equal to five. Now A is no sooner separated from B, than another particle of silk comes in contact, and produces a similar effect. The portion accumulated is now ten. A third comes into successive contact with B, and adds

to the accumulation; and while the rubbing goes on, a series of successive effects is produced by a series of successive unions and separations; for A is no sooner separated from B, than it is brought into that state in which it was before the union, and consequently disposed to part with what it gained by the union. Now if you suppose A and B, instead of being single particles, to be surfaces, all of whose parts operate at the same time, you may easily perceive how the effect would be increased.

In the preceding case I described the capacity of A and B to be enlarged by their union. If it had been lessened, the subsequent effects would have been different;

for in such a case, after the dissolution of their contact, they would be disposed to receive or re-take what they had lost by their union. ---But I will speculate no longer on the consequences of friction, as elucidated from the supposed corporeal nature of the electric fluid, and from the changes supposed to take place on the attractive force of different bodies when brought into very close contact with each other.---Let us now endeavour to account for the other appearances which we have described in this lecture.

I. The attraction of light bodies by excited surfaces is nothing more than the re-action of the fluid on those substances which it

is leaving. If a magnet and a piece of iron be delicately suspended at some distance from each other, both the attracting and the attracted body will be moved. In like manner, while the electric fluid is leaving the silken thread, Fig. I. it carries the thread, to which it is attached, towards the excited surface: but when the silken thread receives the fluid, it is apparently *repelled* by the excited surface; for the course of the fluid is then into the surrounding air, and consequently its direction becomes the direction of the thread.

II. The reason why moisture diminishes the power of excitation will be explained hereafter: but

the increase of excitation by the moderate use of oil, &c. (if the principles I have already laid down be admitted) may in my opinion be ascribed, with some probability, to the more perfect contact which is thus produced, and perhaps to the greater change which is produced by the contact of some than of other bodies.

III. It is obvious, if we have rightly accounted for the effects of friction, that the thickness of a glass cannot materially affect its power of excitation; for the particles at the surface only operate, and the diminution or increase of their capacity cannot much depend on the quantity of the same matter which is internally annexed to them.

IV. If a surface have lost or gained any quantity of electric fluid, it is evident that the signs of excitation will remain till another body is brought near enough either to supply the want, or take away the superabundance. Air is not capable of producing such effects, and consequently, while air alone surrounds an excited body, we cannot well expect that the duration of years would produce any change, either in its positive or negative state.

We have hitherto confined ourselves to the most obvious effects of excitation, or to the changes attendant upon friction in or near

the surfaces of the bodies, which, from the capacity of being excited, are called **ELECTRICS**. As we advance, the machinery we employ, to produce the appearances of electricity, become gradually more complicate. Thus far we have made use only of a dry piece of glass, rosin, amber, &c. and a piece of silk, skin, hair, or leather, as a rubber. For convenience sake, in applying the power of friction, the surface most generally employed by modern electricians, is that of a cylinder; against one part of which, a cushion filled with hair, and covered with leather, is kept with a light pressure, so as to operate successively on a considerable portion of the cylindrical surface, as it moves round.

The contact of the two electrics is generally increased by a piece of silk, which is as wide as the cushion, and, extending from its upper extremity, covers near one-half of the excited surface. --- I shall hereafter give the rationale, and a minute description of this and every other part of an electrical apparatus.

You have seen, in the last lecture, that a body of the fluid was collected on that part of the glass which had just undergone the friction. It is this collected body of the fluid that will cause the appearances observable when the following addition is made to our apparatus.

FIG. IV.

On a piece of glass, AB, (the longer and firmer it is, the better, provided you do not make it either clumsy or inconvenient) fix a metallic tube, DC, in length about two feet, and in diameter four inches nearly. Let this tube be carefully freed from all edges, points, and other prominences: to the side of this tube, which is best known by the name of CONDUCTOR, let a row of points be fastened, such as gh; and while the glass is excited, let these points be placed opposite that part of the glass which has just been rubbed, or which is just quitting the silk. In a few moments you may ob-

serve a brilliant spark passing from the points to the cushion. If you bring your nuckle or wrist near the conductor, the spark will strike into it. An acute noise may be perceived at the same instant, together with a disagreeable sensation in the stricken part; and, in case the metallic tube and cylinder be large, a violent shaking will be felt in the joints and elbows.---The leading circumstances which demand our attention in the preceding operation, are, the sound of the spark,---the varieties dependent upon the various forms of the conductor,---the figure of the spark---its length,---the violence or force of the spark,---and, finally, the brilliancy of the spark.

I. THE SOUND.

WHEN the termination of the conductor is sharpened, by annexing to it a small ball, not exceeding an inch in diameter, the spark is lengthened, and the noise is very much diminished. The noise is loudest when the spark is made to strike from one flat surface to another; for in this case its course is straight, and of course that percussion of the different particles against each other, which causes sound, is most violent. The deflections or zigzag of a spark is a proof that the fluid, in its passage, finds some difficulty (if I may be allowed the expression) in con-

quering the obstructions it meets: therefore, as this zigzag increases, you may always observe that the sound deadens, or becomes less acute. When the spark is made to pass thro' a tube of glass stopped at both ends, the noise is entirely hushed. In making this experiment, the glass tube must be very dry, otherwise it will be impossible to prevent that whole quantity of fluid, which is accumulated near the conductor, from escaping along the sides of the glass.

In a very early period of this science, an electrician observed some analogy between the snapping of a small spark and the explosion of a thunder-cloud. I have often been puzzled, while attempting to

fix upon that circumstance of familiarity which struck Mr. Grey's imagination ; but I always concluded that he owed more in this instance to his good fortune, and his boldness as a theorist, than to his penetration as a philosopher. You will see, however, in a subsequent part of these Lectures, that the acute, cracking, undivided noise of a spark, and the deep, reverberating roar of the lightning, are identical effects of the same cause, differing in degree only, and not in nature.

II. THE VARIETIES DEPENDENT UPON THE FORM AND DIMENSIONS OF THE CONDUCTOR.

Numerous are the differences which result from varying this part of the apparatus. The whole of its

action seems to consist in spreading that fluid which is accumulated on the cylinder to a body of air, which the fluid would not otherwise reach, and in promoting the instantaneous discharge of the loaded air, when circumstances are so managed as to admit of a discharge. If, after the air is loaded, the conductor were annihilated, no change would take place in the accumulation of the fluid; for the whole of the charge would still remain in the surrounding air. On the other hand, the air would never be discharged instantaneously or all at once, unless the conductor be restored to its former situation.

The whole of what I have now said, is proved by experiment.---

When a thick chain, or a great number of balls, connected with each other, forms a conductor; when, moreover, your contrivances are so managed, that the chain or balls, as soon as the air is charged, shall drop into an insulated cup,---on removing the cup, you will find that the conductor has scarcely any signs of electricity: whereas the state of the air, in which the chain was suspended, is scarcely altered; for, upon raising the chain again into the same portion of air, a spark will strike from it, on the application of the hand, or of a metallic substance. What I have just now said, will be sufficient to convince you that, provided your conductor be ever so large, none of the fluid, which passes from it,

is collected in itself: the atmosphere alone is loaded, and to *this only* you must confine your ideas of the *loss or superabundance which takes place*. I call your particular attention to these circumstances, as I have seen the most extravagant errors committed, in the fabrication of some modern theories, owing either to an ignorance or a misconception of them.

The metallic nature of the conductor is the next particular which commands our observation.

If it be made of wood, when applied to an excited surface, a certain portion of the surrounding air will be charged as in the preceding case, but the air will receive the

fluid very slowly : besides, whatever charge is conveyed to the atmosphere by wood, cannot be discharged instantaneously, as in the instance of metallic conductors ; but on the application or approach of a metallic ball, the fluid passes to it in a continued, silent stream, or in the form of a spark attended with little or no sound. In other words, some time is required to unload the charged atmosphere of the fluid which it contained.

If, instead of wood, a piece of glass, of sealing-wax, or any other body which is capable of excitation, be placed in the circumstances of the metallic conductor, no change whatever will take place. I mean to say, that so much air

only will be charged, as we find loaded or charged when no conductor is brought near the excited cylinder.

From this peculiar property electrics have received the name of NON-CONDUCTORS; --- and in the same property we find the reason why metallic conductors, before they can be charged, are placed upon them; for having no power to convey the fluid from one part of the atmosphere to another, they afford no vent or passage for escape to that portion of the fluid which is accumulated around or near the metallic conductor. ---- When any electric is employed to support the metallic conductor, it is then called an INSULATOR, as

it is in many other cases where it is used for similar purposes.

III. THE FIGURE OF THE SPARK.

This depends entirely on the superficial dimensions of that part from which it proceeds, and of that body which receives it.

If the spark be taken from a ball, two or three inches in diameter, its passage will be perfectly straight.

If it be taken from a little ball, half an inch in diameter, the form of the spark will be a zigzag.

But if the conductor should terminate in a point, or in an edge, or

any acute protuberance, the fluid passes to such conducting bodies as are brought near it, in a diverging, uninterrupted stream, or, in case no such bodies are near it, into the air itself; so that, unless the machine be very large indeed, it is impossible to procure any thing like a spark at the distance of more than half an inch from the point. If, however, the point or edge, instead of protruding, be forced back, so as to be on a level with the surface of the conductor, the spark may be formed as completely as if the part from which it struck were perfectly spherical.

Hitherto I have merely shewn you how far the formation of the spark depends on the figure of the part

from which it *strikes*: the same effect, it is to be observed, depends at the same time very much on the figure of the part which *receives* it. No spark is formed when a point is brought near the conductor, or when the body which receives the fluid is made acute: but if the point be buried in a ball, so as not to protrude beyond its surface, the spark is perfectly formed; nay, a metallic point may be circumstanced so as to receive a spark, in case that point be fastened to a metallic substance which is separated from the hand, or any other conducting body connected with the ground by a piece of dry glass, whose length, together with that of the point's separation from the conductor, must not be greater

than the common striking distance of the spark in air.

IV. THE LENGTH OF THE SPARK, OR THE VARIETY OF DISTANCE THROUGH WHICH THE SPARK STRIKES FROM THE CONDUCTOR.

This depends upon several distinct circumstances, viz. The length and diameter of the conductor; the termination from which the spark strikes; the dimensions of the cylinder, or the distance of the cushion from the point which receives the collected fluid; and, finally, the position of the conductor.

1. If the length alone of the conductor be increased, the spark

is rather shortened than prolonged by the change. This effect was observed by Dr. Priestley, in a very early period of his electrical pursuits. If I remember rightly, His experiment was made with many yards length of wire, whose diameter did not exceed one-fourth of an inch. The extremity of this wire, when charged as high as possible, would not yield a longer spark than a conductor of two feet in length, and two inches in diameter. In the "*Scelte D'Opuscole*," may be seen a dissertation of Signior Volta's on the same subject; from which it evidently appears, that several rods eight feet in length, and half an inch in diameter, suspended at the distance of twelve inches from each other,

would not afford that length of spark which he got from a conductor of the same length, and about twelve inches in diameter. Mr. Brook of Norwich has, with great industry, pursued this subject. I have seen him connect near twenty rods (covered with tin foil) about six and a half feet in length, and three-fourths of an inch in diameter, at the distance of near a foot from each other. The whole apparatus, when complete, resembled a large gridiron, suspended by glass rods from his cieling.--- From so large an extent of conductor, I do not remember ever to have seen a spark strike, exceeding six inches in length:--- whereas, from a conductor eight feet in length, and five inches in

diameter, I have often seen sparks strike, nine inches one-fourth long, though the same cylinder was excited in both cases.

From the preceding facts, it is sufficiently clear, that increase of length in a conductor does not contribute to the length of the sparks you produce. The question which occurs from this conclusion is very obvious.

2. Suppose we increase length and diameter at the same time, will the effect be different? I can, from my own experience, answer in the negative. By the most powerful excitation of a cylinder fourteen inches in diameter, the spark afforded by a conductor eight

inches in diameter, and twelve feet long, did not equal half the length of that which I procured from the same cylinder with a conductor equally thick, but shortened to six feet. I have many reasons for believing that a conductor of three feet in length, and sixteen inches in diameter, would have yielded a longer spark than either of the preceding.

Let us, however, proceed to another circumstance, on which the length of the spark very much depends.

3. I mean the proportion of your cylinder's dimensions to those of your conductor. If the diameter of this part of your ma-

chinery be small, the conductor, long before it is *fully* charged, will discharge itself over the surface of the cylinder into the rubber.---

When the conductor is very long, it is a small cylinder indeed that will charge it to a very considerable height. ---- I have seen Mr.

Brook apply a cylinder, four inches only in diameter, to the gridiron conductor which I have already described, and the spark afforded was so violent, that I could hardly endure it : whereas the spark from a conductor of six inches diameter, and about five feet in length, was so soon charged with power enough to strike across the cylinder, as to yield a very trifling spark. The infantine state of this science will not allow us to point

out, with any precision, the space through which the charge of a particular conductor will strike. --- Twenty-three inches, I think, has been the greatest length of a spark afforded by a conductor six feet long, and twelve inches in diameter. I observed, during the operation of this machine, that a longer spark could not be obtained, because the charge passed over the cylinder, which was 18 inches in diameter, to the cushion.

There is a limit in these cases which our experience has not yet determined; but I would call your attention to a fourth circumstance on which the length of the electric spark very much depends.

4. The position of the conductor.

---It was formerly, nay, very lately, the custom to place the conductor so as to form right angles with the side of the cylinder; ---one disadvantageous consequence of this method was, the absolute necessity of using no more than three or four points at the distance of three-fourths of an inch from each other for the collection of the fluid. A great quantity of it, therefore, was allowed to escape to the wooden caps and the cushion. --- Besides, this position removed the conductor entirely out of the atmosphere of the cylinder. The effect of this, and of the other disadvantages which I have mentioned, may be immediately perceived by com-

paring those machines in which the rectangular position is retained, to such as adopt the alteration first observed in Mr. Nairne's patent machine.

5. But the size of the ball, *from* which the fluid is received, is another circumstance connected with the length of the electric spark.

When I have experienced an impossibility of making the fluid strike over more than four inches from the sides of a conductor, I have been generally able to get a spark ten inches long, from an inch and quarter ball, placed at the extremity of the same conductor.--- If the ball be reduced to three-fourths of an inch, the fluid will

strike in successive flashes, and will not pass in a collected body, till the distance between the striking and the receiving body be very much diminished.

Having fully considered the sound, the form, and the length of the spark, we shall now proceed,

V. TO ITS VIOLENCE OR FORCE.

This does not increase with its length: on the contrary, it is evident, from our feelings, as well as from some other tests, that if the spark be received from the body of the conductor, and not from a protruding ball annexed either

to its side or its extremity ; that in the former case it is much more painful than the latter.

Besides, a very large conductor affords but a very short spark, which, compared with others which strike through a body of air seven times longer than that of its own passage, shews a manifest superiority of force. Signior Volta has given particular attention to this subject : he establishes the fact ; but we are far, still very far, in this, as in many other cases, from an approach to any determined law.

Dr. Priestley, judging by the test of his feelings only, has observed, that if a metallic ball be

placed between the conductor and the ball which receives its contents, the force of the spark is much increased. I have often attended to this circumstance, and I have always experienced feelings similar to those described by Dr. Priestley.

In the "Scelte D'Opuscole," may be seen a most prolix and parading description of a method to increase the strength of the spark, by a Signior Litta, whose singular garrulity is not less remarkable than the error which he commits; for, after awakening the curiosity by several quarto pages in praise of his own discovery, the whole terminates with an obscure account of his applying a Leyden phial, instead of a conductor, to the excited cy-

linder, and, consequently, of his mistaking the *violence* of a *shock* for the *force* of a *spark*. But,

6. The most singular circumstance of the electric fluid, in its passage through the air, is the light. ---Provided the receiving and the discharging balls be not distant from each other above half an inch, a continued stream of the most brilliant light will appear during the excitation. When the distance of the balls is increased, sparks, equally brilliant, will follow each other in a most rapid succession. When, however, the distance equals four inches, unless your machine be a very large one, the appearance of the spark will begin to vary, as you vary the

form of what terminates your conductor; for a ball, an inch in diameter, will afford a spark, whose edges will be purplish, and from which several ramifications will diverge, whose colour will be altogether purple or indigo.---The brilliancy of the spark is greatest when it passes through a tube, and its colours are weakest when it is most divided. In case the termination of your conductor be a point, then the brush which passes into the air is of a bluish colour. As we proceed with this science, the singularities of the electric light will be frequently demanding our attention.

I will now remind you, that the detail of circumstances, which I

have just laid before you were the consequences of a very simple addition to our apparatus, or of placing a metallic tube of certain dimensions, parallel or perpendicular, to the excited cylinder. We shall now proceed to make another addition to our apparatus, whose effects, when compared with those we have just enumerated, will be found to differ in degree only, or to flow from the immediate operation of the same causes. As, therefore, what will be said to explain the preceding may be applied with ease to the explanation of many other appearances, I shall go on with a simple account of facts, nor shall I stop in this progress, till you are so well furnished

with experience as to be qualified for taking a more general view of the science.

INSTEAD of the conductor or insulated metallic tube, whose effects, when applied to an excited surface, appeared from the circumstances and facts enumerated in my last Lecture, I shall now substitute a cylindrical glass vessel covered with tin foil on the inside and the outside, having a small part only of its surface uncoated. This part extends from the edge of the glass on both sides to the distance of two or three inches. Connected with the tin foil on the inside of the vessel is a wire, whose upper extremity is in contact with the excited electric. Fig. V. explains the apparatus. During the excitation

of the glass, when thus circumstanced, the following appearances take place. The influx of a torrent of the electric fluid into the inside of the glass vessel; a luminous star at each receiving point of the conductor, which, after the excitation of some seconds, is attended by the appearance of several little streams of the fluid passing from the points to the cushion.

A sudden explosion very soon succeeds, together with a most brilliant display of the fluid in its passage from the inner to the outside coating.

This effect is called the *spontaneous discharge* of the glass vessel, which is known amongst elec-

tricians by the name of the *Leyden phial*.

If, however, at any period of the operation, previous to the sudden explosion or spontaneous discharge, you connect the wire and the outside coating by a metallic rod, with metallic balls at its extremities (see Fig. VI.) the same explosion, in a lesser degree, will take place, and the same brilliancy of light will appear.

But in both cases, if you examine the glass vessel after the discharge, you will find that a small portion of the electric fluid still remains, and is capable of being removed by forming a second metallic communication between the

inside and the outside coating. If, previously to the discharge of the jar, you place one hand on the outside, and then touch the wire with the other hand, the fluid then passes through your arms and body, in which is experienced at the instant a most violent and painful concussion.

A great number of diversities may be observed in the effects I have now briefly enumerated, by the several possible variations which may take place in the following parts of the apparatus.---1st, The glass vessel. 2d, The coating. 3d, The interval of uncoated glass. 4th, The interval of air between the wire and the glass. 5th, The metallic or other substances which

are employed to make the discharge.

I. THE GLASS VESSEL.

If this be very thin, and the uncoated interval not less than an inch on each side of the vessel, the process of charging will be soon followed by a harsh, crashing noise, and in some part of the glass, upon examination, will be found a small hole, from which a multitude of cracks will diverge, so as to give it the appearance of a star. If the glass be very thick, I mean about one-fourth of an inch thick, the spontaneous discharge will happen sooner; but the violence and quantity of the fluid which is now discharged will be

much inferior to what passes from one side to the other when the glass is thinner.

The diversities which proceed from varying the form of the glass vessel are not very numerous or important. When the dimensions of the neck are very small, the wire is so near the uncoated part of the glass, as considerably to hasten the spontaneous discharge.

No change of result takes place if the coated glass, instead of being cylindrical, be either cubical, hexagonal, or of any other figure.

I should add, that all electrics, when similarly treated, display similar phenomena. In common

use, however, glass is generally preferred, because it is most easily moulded into a proper form and thickness. It has, notwithstanding, one quality in which it is inferior to every other electric. Its power of attracting moisture, which, when collected from the surrounding atmosphere on the uncoated interval of the vessel, renders it incapable of being charged without fresh wiping and drying. This inconvenience, when a great number of phials is used, is attended with great trouble. Of all substances which experience has brought to my acquaintance, talc is the most free from disadvantages of this kind. I have charged a lamen of it, and after the exposure of some hours to the air, without any particular

attention to its insulation, I have found its charge scarcely diminished.

II. THE COATING.

The necessity of a metallic coating, for the production of the effects already described, requires your attention. Without this coating, the phial, if clean and dry, will take but a very trifling charge, and even the trifling quantity of fluid, which is thus collected, cannot be discharged all at once. By forming a metallic connexion between the outside and the inside, scarcely any resemblance to an explosion is produced. Instead of a snap, you hear a whizzing noise only; and instead of a spark, a

small stream appears in its passage from the wire which touches the *inside*, to the ball which is connected with the outside. The earliest appearances of the Leyden phial were discovered by putting water into it; but experiments prove that water (even when the vessel is filled with it to a proper height, and when it is covered on the outside to the same height) will not admit of a perfect discharge, as may be easily perceived by the sound of the explosion, and the faint colour of the spark.

Muschenbrook, and some other electricians, who were amongst the first that experienced the electric stroke, must have allowed fear very much to have inflamed their

imagination, when they gave that account of it, in which the loss of kingdoms is represented as trifling, compared to the dangers of bearing a second blow : for the size of their phial, the circumstance of its being filled with water ; the probability that the outside was not covered with moisture or any other conducting substance, so as to answer the coating on the inside ; these, together with many other particulars whose effects tended to lessen the charge, must have rendered the stroke they felt very inconsiderable indeed.

I know of nothing besides the acids which can act as a coating with any degree of perfection approaching to that of the metals.

The acids, however, cannot be laid on with any convenience or permanence, or with any protection against the dangers which are well known to such as are acquainted with their corrosive qualities. I have as yet found no difference between the different metals, in their goodness, as coatings. I have tried brass filings, mercury, lead, tin foil, &c. and they are all equally powerful in their effects.

III. THE UNCOATED PART OF THE GLASS.

If any dust, moisture, or dirt, be spread over this portion of the glass, (agreeably to what I have already observed) all attempts to charge the phial will be ineffectual.

If a small protrusion of the metallic coating extends to the distance of one-third or half an inch on the uncoated glass, the same inconvenience will be experienced in some degree, and this circumstance urges the necessity of having the edge of the coating cut as evenly as possible.

The proper dimensions of the uncoated part, it is my intention to determine (if I can) by some future experiments. I would, however, observe that these dimensions are by no means proportional to the magnitude of the surface, but to the height of charge which the vessel is capable of taking. If the glass be very thin, and the coatings be distant from each other

fix inches, the glass always breaks when the charge is carried to any great height. If the glass be thick, the distance of the coatings may be ten or twelve inches, and no fracture take place. I have stripped the coating off the outside of a pint phial, nine inches high, and two inches in diameter, till it was all uncovered, excepting one inch of the surface, measuring from the bottom. In this case the phial, unbroken, would discharge itself from the wire connected with the inside, over the distance of nine inches on the outside.

When the uncoated interval of the glass is made very hot, the spontaneous discharge is very much hastened: but if the uncoated in-

terval be dirtied to a certain degree, the spontaneous discharge is much retarded, and the phial enabled to take a much higher charge than it would otherwise admit of. I cannot speak the language of Experience with regard to the efficacy of covering the uncoated part of the phial with a good varnish. When experiments are made in a humid atmosphere, I should expect that a great deal of toil might be saved by such an attempt to keep off the moisture.---If the varnish be in the least glutinous, the little particles of dust, which float in the air of the room, will stick, and carry off a vast quantity of the fluid,---especially when the charge gets to be very high.

When the phial is discharged in the dark, the appearance of the uncoated part of the glass is very curious. From all parts of it a croud of luminous streams may be seen pouring, as it were, from the edge of the glass towards the metallic coating. This appearance proceeds from the partial charge which the uncoated glass has received, and which, when the discharge is made, becomes luminous in the several tracts which it follows. I would likewise observe that the cause which operates in this instance, is likewise the cause of that second charge which every bottle is found to have after the first discharge is made; for the uncoated part is but partially discharged, owing to the want of a

good metallic connexion between the several parts of the glass; but the residue, which is thus left, is soon conveyed over the whole internal surface of the phial, and thus communicates to it a small second charge.

IV. THE DISCHARGING ROD.

When this is made of an uninterrupted piece of metal, the electric fluid passes through it without affecting the hand which holds it.

But if the rod consists of two metallic pieces tied together ever so closely, and if you hold it above the juncture during the discharge, you will feel a shock in a small degree. This is owing to the imperfection of the contact which is

formed between the two pieces, and to the small resistance made by the interval of air existing between them.

When the termination of the rod (I mean that which is applied to the wire) is not more than half an inch in diameter, a hissing noise will be heard previous to the discharge, and the explosion will be much inferior to what takes place when a larger ball is used.

If the termination be a point, it will be impossible to procure a discharge with it, unless you bring the point very rapidly indeed towards the jar, or unless the other extremity be separated from the coating by a small interval of air.

To procure a perfectly instantaneous discharge, the rod must be made of metal. all other bodies will either discharge the phial partially, or not at all.

In a subsequent part of these Lectures I shall call your most patient attention to this difference in the conducting powers of bodies. It is time, however, that I should amuse you by breaking, for a while, the plain series of facts which we have, without interruption, extended thus far. Let us now attempt, by the aid of well-founded principles and fair deduction, to obtain a more general view of the science, and penetrate, if possible, into the cause of many, amongst the numerous, effects which we have described.

THE leading principles of our theoretical knowledge in the science of electricity, are the following.

1st, The corporeal nature of that something on whose operations electrical phænomena depend.

2d, That the union of this with other bodies depends on an attractive force, or on the mutual attraction subsisting between that corporeal something, which is called the electric fluid, and the body to which it is united.

3d, That of the electric fluid there is a *certain quantity* only re-

tained by different substances; and moreover, that without some alteration in their constituent parts, it is impossible they should retain more than that certain quantity, or lose any portion of it. Several corrolaries, which flow from the establishment of these leading principles, will, in conjunction with the application of the principles themselves, enable us to explain several electrical appearances.

1st, For the corporeal nature of that something, on which electrical appearances depend, I have already given you my reasons.

2d, To prove the mutual attraction subsisting between the electric fluid and other bodies, nothing is

necessary but the establishment of its corporeal nature; for without the capacity of attracting and of being attracted, it would want one of the essential properties of matter. However, if you have recourse to your own memories, you must recollect facts which establish this principle on the basis of experience. The separation of the pith balls and other light substances, when charged with the fluid, together with the invariable motion of feathers, particles of dust, &c. in the direction of the fluid, shew that the two substances move together, because they adhere or are united to each other by an attractive force.

I would add, that when the elec-

tric fluid escapes from a quantity of water into the surrounding air, it always carries with it a portion of watery particles into the surrounding atmosphere, and thus produces a very considerable evaporation.

The cool current of air, which may be felt when the fluid is passing from a metallic point, speaks a similar language.

But your eyes may bear testimony to the effect of the same mutual attraction in the following experiment. Let the charging wire of a Leyden phial, I mean that which connects the conductor and the inside surface of the glass, be covered with linseed oil: when

the phial is charged highly, the fluid will begin to spit from the wire, and the oil will fly off in the same direction with it, forming, in its various passages, several little beautiful streams. An experiment frequently made by itinerant lecturers, to amuse their spectators, is of the same kind. Let a piece of sealing-wax, in a melting or softened state, be annexed to a conductor: if the conductor be charged, and a metallic ball brought near the wax, the electric fluid, in passing to the ball, will carry with it a continued string of the fused wax.

3d, There is a certain quantity of the electric fluid in all substances, the increase or diminution

of which is altogether impossible, without some previous alteration in the constituent parts of those substances. Numerous are the most decisive experiments which support this proposition. I will present you with a few of the principal.

1. Let a Leyden phial, of any magnitude, be suspended from your conductor, in such a manner as to have no contact with any thing but the wire which fastens it to the conductor: in other words, let it be insulated by a body of air, so as to be eight or ten inches distant from the table the machine rests upon, or any thing else of a conducting nature that is connected with the ground. In these circumstances, the excitation of the

largest cylinder will not communicate the least charge to the phial, as you may be convinced by the application of a discharging rod, or by any one of those numerous particulars which we have described as the invariable attendants of a discharged phial.

2. Let a glass, of the form represented in Fig. VII. be used as a Leyden phial; let the knob A be fastened to a brass wire, which, during the exposure of it to a charged conductor, touches the bottom of the glass AB; let the metallic coating on the outside not rise above one-third the height of the glass; fill the inside to the very neck with any body, either fluid or solid.--- Now in case the vessel, when applied to the charged conductor,

be insulated as in the last experiment, we shall find it incapable of receiving a single atom of the fluid, whatever be *the bulk or magnitude of the body* contained in the glass. I would observe, that the least protuberance on the outside coating, or the incautious approach of a conducting point connected with the ground, or one out of a variety of other minute circumstances, when disregarded, will cause a most important diversity in the preceding experiment. Hence it is, that some persons have been led, by their own slovenly inaccuracy, to reject the only rational theory of the Leyden phial. I would further observe, that the preceding experiments shew only that no addition of the

electric fluid can be made to any substance whatever. I will now proceed to give you experiments with an intention to prove that when an addition is made to one surface of a body, a quantity, equal to what is added, is immediately lost from the opposite surface.

3. Fig. VIII When the phial is insulated, let the metallic ball A, annexed to its charging wire, be brought within a certain distance of the ball B, which protrudes by a metallic connexion from the conductor. Let C, connected by a wire with the ground, be as far from the outside of the coating as A is from the ball B. When the cylinder is excited (or, to use the language of electricians, is made

to work) you may perceive a number of sparks strike from the outside to C, equal to those which contemporaneously pass from B to A. However, this experiment is not the only proof of the proposition in question. If C be connected with the inside of another phial, which is not insulated, you will find that the quantity which has passed from the outside of the upper phial, to the inside of the lower, is exactly equal to that which is accumulated on the inside of the upper phial.

4. You will see hereafter, that³ water, spirits of wine, and some other liquids, will not allow more than a certain quantity of the electric fluid to pass through them.---

On this principle is founded the following experiment, which I design should be acknowledged as a further proof of the proposition in question.

Fig. A F is an insulated phial; B D an insulated tube filled with water; E the prime conductor; C, as in the preceding experiment, a metallic ball, connected with the ground: when the conductor is charged properly, a very faint spark will pass from E to D contemporaneously with another from B to A, and a third from F to C: these sparks will all resemble each other in sound, size and colour. If the tube B D, filled with water, be removed from between A and F, and placed between F and C, the same appearances will take place; for the

water will allow so much of the fluid only to pass from the outside, in this instance, as is conveyed upon the inside in the preceding, and the spark from A to E will now be no greater than it was when BD was situated between those points. A great number of experiments might be easily shewn on the present occasion, which vary a little in their circumstances; but all of them would speak the same language with the preceding, and, in my opinion, remove all doubts with regard to the truth of our proposition, viz. that bodies can receive no addition to their natural share of the fluid, and that such bodies as are capable of being charged, lose from one surface as much as can be accumulated on the opposite surface.

The latter part of the proposition is confined to electrics or bodies capable of being excited.--- Of non-electrics, or such bodies as metals, &c. it is here to be observed, that it is not only impossible to add to their natural share of electricity, but that they are likewise incapable of having their opposite surfaces affected similarly to those of glass, &c. On the contrary, the instantaneous diffusion of the fluid through their whole mass, be it ever so large, and be the quantity of the fluid ever so small, is that peculiarity from which they derive the name of conductors, and which, in a most remarkable manner, distinguishes them from electrics.

THE mode in which the force of attraction operates, when electrics are charged, is capable, I think, of easy explanation.

Let us suppose ABCD, Fig. X. to represent a certain thickness of any electric, at whose surface, and in whose substance, the electric fluid exists as a component part.

In case the particles at one surface AC, be taken away, it is clear that the force which attracted them is disengaged for attracting any uncombined particles which come within the sphere of its activity.

If the force which unites the electric particles within the body, to the substance of that body, be less than that which is active at the surface, then it is clear that the deficiency will be supplied ab intra, or from the substance of the body, and that the deficiency, thus caused, will be again supplied by any similar substance that comes in contact with it; so that the fluid will appear to pass through the body, with an ease proportionable to the smallness of that force within the body which obstructs the removal of its inherent particles.

If the force which unites the electric fluid to the internal parts of the body, be greater than that which is active ab extra, the defi-

ciency then will not be supplied from the body itself: none of its inherent particles can be removed, and the attractive force can operate only at one of two places, either by immediately attracting to the surface, where it exists, the due quantity of the fluid, or by accumulating the same quantity at the opposite surface, provided the intervening thickness does not remove it to a distance which the attracting force cannot reach.

FIG. XI.

In ABCD, the black spots represent the electric fluid; the small circles the integrant particles of the electric.

If the black spots be taken away from the circles lying in the direc-

tion of c, f, it is obvious that those circles will be in force to act upon the spots in the direction of b, e, which will give way, provided the force, by which they are attached to their adjoining circles, be less than the force of the circles which attract.

The same changes will take place under similar circumstances, between b, e, and a, d; and so on, ad infinitum, or to the utmost extent of that body whose peculiar property is that which I have just described.

But when the spots in the line c, f, are removed, if those in the line b, e, are too strongly attached to be displaced, then it is obvious

that the force, caused by the absence of the spots, will continue active, till a supply is brought within the limits of its influence, at the surface BD, or at the surface AC. At BD, the fluid may come immediately into contact with the attracting surface; but at AC, it cannot be brought nearer than a distance measured by a, c.

I. From the explanation I have given, we may learn to qualify the general assertion, “ that a body cannot contain more than its *natural* share of the electric fluid;” and we may likewise furnish ourselves with reasons in confirmation of it, in its qualified sense, additional to those which are derived from experience.

When the body is charged, the force of the circles, in the line c, f, acts at a greater distance than it does while the body is in its natural state, and therefore must be diminished; whereas it ought to be increased, in case more fluid was collected at AC, than had been previously lost at BD.

There are cases in which a quantity of fluid is, as it were, let loose, and rests, apparently uncombined, on the surfaces of electrics. That part of a glass cylinder, which has been recently separated from its contact with the rubbing silk, is thus covered; but the circumstances of this fact are very different from those of a charged electric. The surface of the glass

cylinder, opposite to that on which the fluid is collected, is not at all affected, or, when examined by the most delicate test, shews no signs of negation.

It has, in connexion with the preceding assertion, been strenuously maintained, "that no negative surface can exist without a correspondent positive." This cannot be true; for that part of an electric, which has been excited negatively, is precisely in this state just after it is separated from the rubbing substance. This may be at any time proved by examining the surface opposite to that which has been excited. Indeed, signs of negative electricity may be discovered on the surface of an

excited solid, or where it is impossible that a correspondent positive should exist.

The *general assertion*, then, "that an electric can contain no more than its natural share of the fluid," must be confined to charged bodies, or to such as are capable of having deficiency existing in one part, or on one surface, supplied by a communication with the other.

II. From the explanation I have given, the progress of changes which takes place, while any electric is charged, may be easily conceived.

While the rubbed parts are together, a strong attracting force is

in action, which collects a quantity of fluid from every connected substance, whose adhesive force is inferior to that which attracts.

If no other connexion exists than between the cushion and the air surrounding it, then no more fluid can be collected, than what that portion of air can yield from its natural quantity. Let the surface of the cushion be enlarged, then a greater quantity of fluid will be collected; but let the surface of the cushion be connected with that of the whole earth, and the friction will then operate upon an exhaustless store, and of course every limit to its effects be removed.

When the rubbed parts are separated, the accumulated quantity

of electric fluid rests on the surface of the glass, and readily forms a positive in one part of the atmosphere, correspondent with the negative, which the friction must have previously caused in another. If, when this change has taken place, one surface of the electric, to be charged, be brought into contact with the positive portion of the air, there is then no attractive force active to produce any change; but let one surface be connected with the positive portion of the atmosphere, and the other with the negative by conducting substances, then the superabundance of one part of the atmosphere, in contact with one surface of the electric, enables that portion of the atmosphere, which is deficient, to sup-

ply itself from the natural share of the opposite surface of the electric.

EFGH, Fig. XII. represents a body of the atmosphere loaded with an additional quantity of the fluid.

ABCD, the correspondent negative. It is clear that the fluid, contained in EFGH, is kept in its situation by the attractive force, which is rendered active by the deficiency at ABCD, and that the inside of the glass jar I, in contact with it, cannot operate; for in its natural state, its force cannot be equal to that of the negative, ABCD; but as soon as you connect its outside, K, with ABCD, the insuffi-

ciency in that portion is supplied the more easily, in proportion to that diminution of the attractive force at K, which is caused by the nearness of the superabundant fluid, and by the contemporaneous operation of the deficiency at ABCD.

Analagous to this series of changes, which takes place between the different portions of a charged atmosphere and the opposite surfaces of an electric, are the appearances of two electrical jars, connected with each other.

Fig. XIII. AB represents a coated jar, connected with another, BC, by the wire B, which is fastened to the outside of the upper and the inside of the lower jar.

When any quantity of the fluid is introduced at A, a quantity equal to it passes from its external surface B to the inside of the lower jar, where an accumulation is formed, and a proportional quantity is separated from the surface D.

Though the deficiency at B is in connection with the superabundance at C, it cannot be supplied from it; for the attractive force at B is exercised upon the quantity accumulated on the correspondent inside surface A of the same jar; and moreover, the accumulation, with which it is in contact, is kept there by the attractive force at D.

But if you connect, by a metallic rod, GH, the positive at A,

with the negative at D, then an opportunity is given for the attractive force at B to operate upon the accumulation at C; for this power is released by the contemporaneous action of the negative at D, upon the positive at A: a discharge, therefore, of both jars takes place at the same instant, and experiments prove, what might be inferred from the general explanation I have given, that this discharge has the force only of one jar.

Let the jars be separated from each other by a small interval of air at E; and while the fluid, in passing from A to C, appears luminous at D and H, the fluid, in passing from B to C, will appear

luminous in the above-mentioned interval E.

I have taken some pains to convince you that the operation of an attractive force alone is sufficient to account for all the phenomena of charged electrics---because my ideas on this subject are very different from those of Dr. Franklin, who has adopted a theory which, in my opinion, is exposed to insuperable objections.

He supposes that glass has wider pores at its surface than near its centre, and that the smallness of the pores near the centre will not admit the particles of the electric fluid, which he considers as too large to pass through them. The

fluid, therefore, is accumulated at the surface, and there exercises a repulsive power on the particles which are attached to the opposite side."

The existence of different sized pores in the glass is gratuitously assumed, and in case it was admitted in the single case of glass, yet in other cases it cannot be even supposed without the grossest absurdity. The instance taken from the power of charging the thinnest lamen of talc, is singularly strong against this theory, as its surface and centre are so near each other, as to preclude all ideas of difference in the size of their pores.

Besides, how does this theory account for a superabundance and correspondent deficiency in two contiguous plates of air? This is a case in which no contraction of pores can exist to prevent the immediate restoration of the equilibrium.

I cannot easily grant the repulsive power of the particles assumed in this theory. There is no other fact in electricity which may not be readily accounted for without the aid of this power; and in the present case, if what I have said be admitted, there is no necessity of having recourse to its operation. I would add, that the strong attraction of the negative to the accumulation on the posi-

tive surface, is admitted by Dr. Franklin. Indeed it is impossible, on any other principle, to account for the adhesion of the superabundant particles to the glass; for if the surface nearest these particles has lost none of its natural share, then, from what I have said, it can have no influence on the particles alluded to. The attraction of the negative surface is, therefore, alone active in this case; and when so much is granted, where is the necessity of a repelling power to account for the effect in question? for if the whole glass can contain a certain quantity only, when an addition is made to one surface, that which adhered to the other must readily go off to supply

a deficiency that is formed elsewhere,

III. The principles which I have endeavoured to explain and to establish, furnish us with an obvious reason for the power of the discharging rod. Conductors, you should remember, make little or no resistance to the passage of the electric fluid. The attraction of the outside of the glass, to the fluid collected on the inside, diminishes in proportion as the thickness of the glass increases, or the distance between the accumulation and the part which attracts it. When, therefore, you connect the outside and the inside of a phial by a metallic rod, you do nothing more than annihilate all distance between the body which attracts and that

which is attracted. I will explain myself by a figure.

FIG. XIV.

A, represents a particle of the electric fluid, which is kept in its situation by the attraction of the glass at B. It is prevented from passing to B by the resistance of the intermediate glass. But the body of metal, CAB, is a conductor, and makes no resistance to the passage of the fluid: consequently the surface, B, when the metallic connexion is formed, must operate with full efficacy on the particles at A; as in the direction of CB, all resistance is equal to nothing: in other words, the effect is the same as if the thickness of the glass were at once annihilated.

IV. Let us now see how, from the principles already admitted, the action of the metallic coating may be explained. It has been already observed, that without the coating no instantaneous discharge can be made. If, however, you can imagine a metallic discharging rod at the same instant to touch every particle on both sides of the glass, you must conclude, from the method of reasoning used in the last article, that every particle of the accumulated fluid would be discharged at once. The metallic coating operates like such a discharging rod; for when both coatings are connected by a good conductor, the same opportunity is given for every particle to be influenced by a more powerful ope-

ration of the negative surface, than can be exerted through the medium of the glass.

V. We have hitherto applied our principles only to glass and other solid electrics. Air is capable of shewing appearances in most respects similar to what we have been explaining: there are, however, several obvious varieties; but the leading circumstances, to which I would call your attention, are the following:---That a certain body of air is capable of being divided into two portions with regard to electricity; the one of which has a superabundance, and the other a corresponding deficiency; that the quantity, however, contained by the whole, is always

the same; that the equilibrium between the two portions may be restored, when a metallic communication is formed between each particle in the positive, and each particle in the negative portion; that the air is alike impermeable to the fluid with glass and other electrics, and that there is an intermediate part between the positive and the negative, which retains only its natural share.

The foregoing particulars are all founded in such facts as are nothing more than a repetition of the experiments which I have described as belonging to the Leyden phial; with this difference only, that, in the one case, we use glass; in the other, two plates of air;

which, by the use of a certain apparatus, are as easily charged as the opposite surfaces of a Leyden phial. Indeed, the phænomena of the common conductor are the consequences of such a process: this will appear, if we attend to that explanation of them which I shall now give.

Conceive of any conductor, as surrounded by an atmosphere, containing a superabundance of the electric fluid: to this atmosphere there must be somewhere a corresponding atmosphere in a negative state. The smallest of such atmospheres must, in most of its parts, be of so much extent as to touch the ground. A discharge, therefore, of the air surrounding the

conductor cannot take place, till a connexion is formed between it and the ground, which, in this case, operates exactly like the coating of a Leyden phial. The chief difference between air and solid electrics is, that no part of the accumulation penetrates the latter; but the whole superabundance of the electric fluid in air is mixed with the particles of air, and causes a separation of them. On this circumstance depend several of the singularities which belong to what is commonly called the electric spark. However, before these can be accounted for with any plausibility, it is necessary that I should previously call your attention,

VI. To the explanation of a

fact which frequently takes place in the Leyden phial, and which takes place likewise between the positive and negative portions of air, whenever a spark strikes from the conductor to a metallic ball, placed at some distance from it, and connected by a good communication with the ground,---I mean now to give you, if I can, some idea of the cause which operates when the interval, dividing the positive from the negative surface, is perforated. It has been already shewn to you, that the accumulation is separated from the deficiency by a portion of glass, which retains its natural share with such a degree of attraction, as not to be overcome by the power which acts at the negative surface. From

this proposition, it is a necessary corrolary, that when the power at the negative surface is so much increased, as to overcome the adhesion of its natural share of the electric fluid to the intervening glass, then the glass will shew the usual effects attending the loss of what enters into any body as a constituent ingredient.

Fig. XV. If, by the accumulation at AB, so much is driven off from CD, as to enable it, by any means, to take a portion of its natural share from EG; we are then, I think, to expect the consequences I have already mentioned. Now the principal question in the present case is the following:---When is the attraction at CD likely to overcome the adhe-

sion of its particles to EG? I answer, that the effect must be early or late, in proportion to the power by which the particles adhere to EG. The attractive force at CD evidently increases as the accumulation increases at AB. I should therefore conclude, that different electrics will require greater or less accumulations before they are perforated.

This conclusion is agreeable to experience, as well as to theory. But it may be asked, Is not the whole power of CD exercised upon the accumulation at AB? How, therefore, can it operate on the particles of the interval EG? I answer, that the particles at EG are nearest to CD, and consequently would be the first to unite

with CD, if it were not for a *different power* which operates, and which is no sooner conquered by the increase of CD's attractive force, than the particles are immediately removed, and followed by the particles accumulated at AB.

Fig. XVI. Suppose b to be a particle of matter within the sphere of a's attraction, let c, d, be two other similar particles of matter, nearer to a, and consequently more strongly attracted, but fastened by a cement or any adhesive substance, which has only a certain degree of power; b, if moveable, will be drawn towards a, nor would the other two particles c, d, be removed till a's attractive power was greater

than the adhesive power of the cement. As soon as this happened, then c, d, would immediately quit their situations, and b would come into contact with a.

If you will admit the steps of the preceding rationale, you must conclude, that to accelerate a perforation through glass, or any other electric, nothing is necessary but to confine the accumulation as much as possible to one point; for the larger the surface which any accumulation is spread over, the more must be expelled from the opposite surface, and consequently the longer will you be, before you reduce it to that state of negation, in which the attraction of the internal parts of the glass will yield their natural share.

I will explain my meaning thus : Suppose a surface of twenty feet received an accumulation, which I estimate at 5000; if 7000 were all it could bear, or were all which the outside could part with, it is evident that this accumulation, reduced to ten feet surface, would burst through the glass; for in that case the opposite surface would lose 10,000, which is 3000 more than it could part with.

FIG. XVII.

EXPERIMENT. Charge the phial, ABCD, as high as it can bear; bring EFGH, which is ten times less than it, within its circuit. If a metallic communication be instantaneously formed between A

and E, and G and D; provided the neck of the small phial be so long as to prevent the charge from passing over the uncoated part of the glass, an explosion will take place, and the small phial will burst. In this experiment, it is obvious, that by the instantaneous accumulation made on the outside of the small phial, its inside is suddenly brought into that state which I have already described as necessary for the perforation of the glass.

FIG. XVIII.

Exp. I would now produce a very striking fact, similar to the preceding, in which the glass is not coated, and in which a very small accumulation, because it is confined

to a single point, forces so much off the opposite point, as instantly to perforate the glass. ABCD represents a phial filled with oil; e is the point of a wire touching the inside of the phial; f is the point of a wire placed exactly opposite to e, and communicating with the ground. A spark, passing from the conductor G to the ball A, will immediately strike through glass. A conductor, in length one foot, and in diameter three inches, charged by a cylinder not exceeding four inches in diameter, will produce this effect in glass whose thickness equals one-eighth of an inch. The design of filling the tube with oil, is to prevent the accumulation from spreading, which would be the case if the oil, as a non-conductor, did not prevent

the effects of that coating of moisture, which would otherwise adhere to the sides of the glass. The oil is unnecessary, if you use talc or any other very dry electric. By substituting at e, instead of the point, an inch square surface of tin foil, and an equal surface on the opposite side, you will find it necessary to increase the number or the size of the sparks before you acquire the accumulation necessary for breaking the glass. As the glass becomes thicker, the accumulation must, for many reasons already enumerated, be increased. A small Leyden phial may be made, by this means, to strike from one point to another through glass three-eighths of an inch in thickness.

A fact, which at first sight appeared both to my friend Mr. Brook and to myself very puzzling, is, I think, easily accounted for in a manner similar to the preceding. He coated the inside of a phial with cement, and the outside with tin foil. A wire, which touched the cement, was applied to a charged conductor, and the phial at the point of the wire was instantaneously broken. In this case the accumulation is confined to one point, and therefore produces the described effect. I found that if the phial were coated on the inside with cement, and then covered with tin foil, that the usual charge and discharge would take place without any attendant fracture.

I proceed, however, to another conclusion, which the principles and facts, already enlarged upon, render (in my opinion) very probable. It is evident, I think, that when the glass or electric is thickened beyond a certain limit, the particles on one side may be removed to such a distance as to have no attractive influence on whatever accumulation may be made on the opposite side. This is the cause of our inability to charge a very thick phial, and this is the cause why glass of a certain thickness cannot be perforated by any force, if applied as in the preceding experiments.

FIG. XIX.

Expt. Let ABCD represent a surface of plate glass, about four inches square; bring the point of a wire, connected with the inside of a charged jar, to touch the glass at the point E. Let a point on the under surface of the glass, directly opposite to E, be touched by another wire connected with the outside of a charged jar. To prevent any moisture from conveying the electric fluid over the surface of the glass, I have always buried it in oil, or some resinous fluid; and in making experiments upon it, thus circumstanced, I have observed,

1st, That I could never make the highest charge strike through a thickness of glass exceeding four-tenths of an inch.

2d, That when I used points, it made no difference whether I applied the force of one or ten quart jars; the effect was always the same.

3dly, When surfaces, of different dimensions, of tin foil, were placed in the situation of the point, then, as the surface of the tin foil increased, so was the number of jars increased, which were necessary to perforate the glass.

The greatest singularity observable in the preceding facts is, I.

think, easily elucidated. You see that ten phials would not strike through a greater thickness of glass than one. The perforation (as we have already shewn) depends upon our forcing, from a particular portion of one surface, a certain quantity of electricity. But this cannot be done if the glass be so thick as not to allow the negative to approach so near the positive as to exercise its attractive force.

The facts in which a battery appears to produce a greater effect on electrics, than a single phial, are those in which the first principles, already applied, very frequently would lead us to expect such effects. I will enumerate a few of them.

Fig. XIX. If the accumulation at E be confined to a point, it is evident that the opposite point can afford but a very little loss before a perforation takes place. If the surface at E be increased, to bring the opposite side into that state in which the perforation takes place, a greater accumulation of the electric fluid is necessary: nay, the surface may be increased, so that the contents of a large battery would be necessary. Thus now, if the surface at E be one-eighth of an inch, and if twenty particles are to be forced off the outside previous to the perforation, it would make no difference whether you accumulated forty or twenty on the opposite side; for in both cases the cause would be adequate

to the production of the effect. If the surface be increased to one-fourth of an inch, then to produce the perforation, an accumulation of forty particles would be necessary. If the surface be half an inch, then eighty particles would be necessary, and consequently four times the charge would produce the perforation of one-eighth. These speculations are very much confirmed by the facts which I have shewn to you, and from which, indeed, I originally deduced them.

But again, the principles I have enlarged upon, have sufficiently explained to you the reason why the charge of a *jar* passes more easily from a point than a surface.

With very little exertion of mind we may apply the same reasonings to the quick discharge made by a point of an electrified body of air, and to the insulating power of a surface or ball of a certain magnitude. I must recur to a figure (Fig. XV.) which I have used before.

Suppose AB and CD to represent the negative and positive portions of air which is charged; it is evident, from what I have already said, that every part of the surface, CD, must be deprived of a certain portion of the fluid, before the accumulation at AB can force its way through the interval EG. It must, moreover, appear, in case the surfaces were perfectly flat and opposite to each other,

that before the perforation can take place, a loss must be made at CD, which would be great in proportion to the area of its surface; and unless an inequality in the resistance made by the interval, EG, should produce a discharge, the accumulation must be continued at AB, till every part of EG gave way at the same instant; for while the surfaces are alike, the influence of the attractive power at each particle, g, in the plate of air, upon each particle, h, must be equal, and previously to the discharge, the resistances made at all the several intervals, from g to h, are to be overcome.

Now let one of the lines, gh, be shortened, while all the rest con-

tinue the same; or let a metallic point be carried out to *e*, and then the whole attraction at *CD* must operate in the direction *ch*, and must produce that state in which the fluid passes through a non-electric to supply the negative surface, while any accumulation continues at *AB*. Now if this account of the fact be admitted as true, you will, I apprehend, immediately perceive why a point extending no further than the surface of the conductor, though it be in the middle of a cavity, has no effect; for in that case, what is represented by *gh*, is not shortened. I have no doubt that one difficulty still presses upon your minds. I mean that of explaining how the whole attractive force operates instant-

neously at ge. I think a single experiment will remove your difficulty.

Fig. XX. Let A, B, C, &c. represent so many distinct portions of electric surfaces charged positively; G, H, I, &c. their correspondent negative surfaces. As soon as you supply the deficiency at G from A, by a metallic rod, G will take a new charge immediately; for the negation at H is instantaneously divided between it and G, and the accumulation at B is instantaneously divided between it and A, and the same division between C and B, and I and H. Now by diminishing the dimensions of each little superficies, and multiplying their number, you come at once to the difficulty in question.

The operation of the metallic rod is similar to that of diminishing the distance gh , in Figure XV. and if the portions, A, B, &c. represent single particles, the modes of operation which I have pointed out, must take place a fortiori.

But again, it must appear to you in this case, as in others which I have made use of to explain the resistance of glass, that in placing a small surface, instead of the point e , (see Fig. XV.) you increase the intervening resistance of e, h ; and hence is clear the reason why balls of different dimensions insulate more or less, because their surface will increase in a certain proportion to their dimensions. The prin-

ciples upon which I have amplified might be applied to a multitude of known facts, which will occur to you, if you be ambitious after any degree of experience in this science.

I will, however, call your attention to one fact more, and that is the superiority of length in the spark yielded by short conductors of a large diameter, to that of a spark yielded by conductors of a great length and small diameter. We see, in the case of the Leyden phial, that in proportion to the accumulation on any given surface, so will the thickness of the glass be through which the perforation is made.

The same effects follow, when the accumulation is made in a body of air surrounding a common conductor, and consequently the same difference takes place in the interval of air through which the charge passes; that is to say, the larger the body of air, through which any given quantity of the electric fluid is dispersed, the larger will the surface be of the correspondent negative. Vice versa, As you diminish the body of air, you heighten the charge, and increase or magnify its effects. But it is clear, that when you lengthen your conductor, you increase that quantity of air which you charge, much more than when you increase the diameter of it. To be convinced of what I have now advanced, we

need only cast our eyes on the figures representing Volta's rods and Brooks's gridiron: in both these instances, the apparatus is so formed as to conduct the fluid over an extent of atmosphere, to which, when compared with it, the atmosphere surrounding a conductor three feet in diameter, and eight feet long, is trifling.

It is time I should once more quit the region of speculation and theory, and return to the enumeration of plain facts.

ON THE ELECTROPHORUS.

The facts I have hitherto described, and enlarged upon, were the consequences of two very simple additions to our apparatus.

You have as yet known nothing of electricity, besides the numerous effects of placing, either a common conductor, or a Leyden phial, near your cylinder, soon after, or during the friction of it. The astonishment of electricians has been very much awakened lately by that discovery of Signior Volta's, whose appearances I shall now display, and hereafter endeavour to explain.

FIG. XXI.

A is a round plate of brass, copper, or wood, covered with tin foil, and carefully freed from all edges and points. To this plate Signior Volta has given the name of scudo. — B is another round plate of wood or brass, or,

indeed, any other substance covered with a varnish. Some prefer a cake of sulphur; others, a coating of sealing-wax, dissolved in spirits of wine; and others, a coating of rosin, dissolved in oil of turpentine. To the upper plate is annexed a stem of glass, or of some other non-conducting body. The appearances which depend on the use of this apparatus are the following:

If the surface of the lower plate be well dried, and then rubbed till it shews signs of electricity; and if in this excited state, the scudo be placed upon it, connected at the time by any conducting substance with the ground, let the connexion with the ground be suddenly broken,

and the scudo raised by the aid of the glass handle or stem, and several curious effects may be observed.

1st, A spark will strike to any conducting body, which is brought near the scudo.

2d, The scudo will always be found in a state opposite to that of the excited plate, (i. e.) positive when the plate is negative, and negative when the plate is positive.

3d, If the scudo, after emitting a spark, be placed on the plate again, and again connected with the ground, and raised by the handle, the same appearances will be discovered without the aid of

any fresh excitation ; nay, the repetition of this process may be made for hours together, without any sensible difference of effects, provided the apparatus be kept perfectly free from all accidental moisture, feathers, hairs, dust, and other light substances which float in the air of almost every room.

4th, If the scudo touch the electric in a few points only, a considerable spark may, notwithstanding, be drawn from it, by proceeding as I have already described.

5th, The force of the electrophorus, when much weakened, is said to be very much increased by placing a charged phial on the lower plate, and by gradually discharging

at one surface, while the other is in contact with the excited surface of the electric. The same effect is said to be produced by conveying the strong charge of one scudo into that of the electrophorus, which is weakened.

Hitherto we have had no other rational attempt to explain the phenomena of this curious instrument, than that made by my excellent friend Mr. Bewly, in the Monthly Review; who says, “that the excited plate acts upon the electric matter naturally contained in the upper brass plate, and repels from it a part of its natural quantity, in the form of a spark, at that part where the finger is applied to it. If (says

he) the brass plate, in this state, is lifted up by its handle, it will receive a spark from the finger." The repetition of this effect he ascribes to the retention of its virtue by the electric, which does not lose any of its own electricity. This mode of explaining accounts only for the electricity where the excitation produces positive electricity: the explanation must be reversed in the case of negative electricity; but it is exposed to objections, which strike me as insurmountable: 1st, It calls in the aid of a repellent power, where I think it is not at all necessary, and previous to any decisive proof of the operation of such a power in this science. 2^{dly}, I object to the repulsion or attraction of electric matter from the SCUDO. This

language is inaccurate. The scudo operates only as a conductor, and the whole effect is the consequence of a surplus or deficiency in the air furrounding the scudo.

By attending closely to the singularities of the electrophorus, you will be led, I think, to agree with me in considering it as differing from the common cylinder in one circumstance only, and as owing its effects to the very same causes, by the aid of which we have already accounted for the operation of every other electrical machine. The similarity of the instruments will appear by attending to the following particulars:

1st, An insulated cushion, covered with tin foil, and applied to

the cylinder, will shew all the appearances of the electrophorus.--- The experiment I allude to, I would describe thus; Fig. XXII. AB is a piece of wood made hollow, and perfectly free from all edges and points: it is covered with tin foil, and insulated by the glass stem CD; a cushion is placed in it, and employed agreeably to the common mode in exciting the cylinder EF. No electrical signs, however, will be discovered, while the insulation CD is complete, be the cylinder turned round ever so frequently: but if you stop the motion, and place your finger upon AB, and then remove AB from its contact with the glass, on the application of your knuckle, AB will yield a spark, if brought in

contact with the glass a second, a third, and a fourth time, without turning the cylinder, or repeating the friction.

By a process, similar to what I have already described, repeated sparks may be obtained, with all the circumstances attending them, which we have described as the effects of the electrophorus. Now by placing a glass plate in the room of EF, and by supposing AB to cover the whole plate, you form an electrophorus without producing one single circumstance of diversity from the common cylinder. But again, if after you have excited the electrophorus, you take away the scudo, and apply a number of metallic points connected

with the ground, to the excited surface, and then apply the scudo, no more sparks can be obtained without a fresh excitation. This is exactly similar to what takes place in working with the cylinder; for, as soon as the excited part has passed the cushion, a multitude of points are applied to it, which reduce the excited part into its natural state, and render it incapable of shewing electrical signs till it comes again into contact with the cushion. Once more, if the surface of the electrophorus be excited, and metallic points be applied to it, connected with an insulated conductor, the conductor will be discharged just as it is when applied to an excited cylinder.

I need not, surely, amplify any longer on the similitude of an electrophorus to a common machine, or on the possibility of making the latter shew all the phenomena of the former. I shall now beg your attention to those effects, which made this instrument, when it was first discovered, appear so wonderful, and so different from all others.

Why, without any fresh excitation, does the application of the scudo, and the finger in the electrophorus, and the insulated cushion in the case of the cylinder, yield *repeated sparks*? You may remember, that I have already ascribed the separation of the fluid from electrics, to that change of

attractive power which necessarily takes place when bodies, different in their nature, are brought into close contact. In the present case you may see the operation of this cause, by attending progressively to the various steps observed in exciting the electrophorus.

The hair skin, the silk, or any other body, which you employ as a conductor, is brought into perfect contact with the surface of the electrophorus. In this state the bodies attract more or less, united, than they do separately; consequently, a portion of the fluid is taken from, or conveyed to the earth through the hand, or whatever else is connected with the rubber. Let the hair skin be se-

parated from the surface of the electrophorus, and that surface will either have a quantity accumulated, which it is ready to part with, or it has lost a portion, which, when the rubber is removed, it will be eager to attract from any approaching body. In other words, you will find the excited surface either in a positive or negative state. Let us first consider it in a positive state.

By placing the scudo on it, thus circumstanced, why does not the scudo yield a spark on the approach of a finger to it? or immediately convey to any conducting body, which is near it and connected with the earth, the superabundant fluid which is accumulated

on the surface? I answer, that as soon as you bring the surface of the metal into contact with the excited positive surface, the law of attraction is immediately altered. The two surfaces attract more than either would singly, and are not only able to retain all the superabundant fluid on the excited surface, but to take more, which is evident from experiment. When, however, you remove the scudo, the union which causes a superior attraction is immediately dissolved, and there is nothing to prevent the accumulated superabundance from striking out of it in the form of a spark.

It may be asked, why, if this theory be true, is it necessary to

rub the surface of the electric, before its contact with the scudo produces the effect in question? I see no absurdity in supposing that the attraction I have alluded to so frequently may be helped by an accumulation of the fluid on the surfaces, just as a small drop of water or oil, expanded on their surface, promotes the adhesion of two pieces of glass. Besides, the rubbing, when employed, operates in a variety of ways favourable to the excitation. But again, in support of the hypothesis I have given, observe, that this is not the only instance in which the union of a surface of metal, with that of an electric, produces electric appearances. Our amalgams operate on this principle, and I have al-

ready enumerated several other similar facts; to which may be added, a very decisive experiment made by Mr. Bennet. He heated a well polished marble plate, so as perfectly to free it from all moisture. He then placed upon the surface a brass plate ground, which he pressed close to the marble with a metallic rod. When the brass plate was separated, it gave evident signs of the additional fluid, which had been collected by its simple contact with the metal.

The reverse of the case which I have just now explained, must be obvious to you. If the two surfaces, when joined, will take less than during their separation, by their union they will lose a certain

quantity, and in the act of losing will give signs of positive electricity. But I shall recur to the explanation of this and other similar appearances, when I have described the effects of

THE INSULATED ELECTROPHORUS.

FIG. XXIII.

AB is a rounded piece of wood, covered with tin foil, and resting on an insulating stand, CD. On the surface of AB is to be placed the excited plate: ab, is a wire with a brass ball, to which are appended the pith balls g and h.

1st, After the hand has been laid on the scudo in contact with

the plate, not the least signs of electricity are discoverable on the removal of the scudo.

2d, If both surfaces of the excited plate be connected by an insulated metallic discharging rod, and if the scudo be afterwards raised; in this case, again, no signs of electricity will be discovered.

To succeed in this experiment, the resinous plate should be completely freed from all points; and before the junction of the scudo, every part of the apparatus, excepting the excited surface, should be carefully purged of all adhering electricity.

3d, The scudo is then only

charged, when the communication between itself and the plate is continued to the ground; but the pith balls, during this process, do not separate, till the scudo is raised: in consequence of the elevation, they suddenly diverge, and when the scudo, *undischarged*, is put down again upon the plate, they instantly close; but when the scudo is *discharged*, and then placed on the excited surface, the divergence is continued.

In this situation, by forming a connexion between the upper and lower sides, a small charge is communicated, which grows less and less with each repetition of the process.

4th, A spark, after the separation, may be taken from the brass plate, nearly as powerful as that which strikes from the scudo, but always of an electricity opposite to that of the scudo.

The preceding are some of the most remarkable appearances of the insulated electrophorus, when the excitation is that of *friction*. The varieties are numerous, which take place when the excitation is that of communication.

5th, When the negative surface of a charged phial is placed on the excited surface, by bringing the hand into contact with the opposite side of the phial, a spark is instantly communicated, and the

pith balls, g and h, separate negatively.

If the phial be taken off, and the scudo placed in its room, no change is observable on the subsequent removal of the scudo, provided, that no communication has been formed between it and the ground. When such a communication is formed, a charge is communicated, and the scudo and the balls are in opposite states of electricity.

If the positive side of a Leyden phial be placed on the excited surface, the pith balls separate positively. You will observe that these experiments are made with a resinous substance.

6th, The appearances of the pith balls and scudo are materially varied, if the Leyden phial be applied to the electrophorus while the scudo is in contact with its excited surface. If the negative side of the phial be applied, and a spark be taken from the positive, the pith balls immediately separate negatively; but, on taking up the scudo, they immediately close, and as rapidly separate again positively.

If, after the phial is removed, the hand be applied to the scudo before it is raised, a small spark strikes into the hand; but on raising the scudo, the balls close and separate instantaneously, and give signs of positive electricity.--

If the scudo and the brass plate be connected, either by an insulated or uninsulated discharging rod, the balls close and separate again, and the scudo, upon being raised, receives a vigorous negative spark.

It is obvious that in all the preceding experiments, the brass plate continues unchangeably adherent to the lower surface, while the scudo only, or the conducting substance in connexion with the upper surface, is immoveable. It is of importance that we should know the consequences of making both the metallic surfaces moveable.

But this is not an easy matter; it is very difficult to get a resinous substance thin enough, and at the same time firm enough, for the

purpose. The perfect lamina of talc, which I have been able to procure, are too small to be used with any satisfaction; I have, therefore had recourse to glass for the purpose. The result of my repeated trials are the following:

7th, Having substituted a glass plate, about twelve inches in diameter, and one-fourth of an inch thick, in the room of the resinous substance, and having rested it on a ground metallic plate, five inches in diameter, and well connected with the pith balls g and h, I exposed it to the sparks of a conductor charged positively, and kept my hand at the same time in connection with the wire ab. The plate took a considerable charge; its upper side was unequivocally

positive, and its lower side negative. I placed the scudo on the glass thus charged, and, approaching it with my hand, I received a spark. I then approached ab with my hand, and received another. By alternate approaches of this kind, four or five times repeated, the sparks became weaker and weaker, till they disappeared; the scudo was then raised, and was strongly negative; but the pith ball, on the removal of the scudo, closed and separated positively.

I then made the lower the upper surface, and, placing the scudo upon it, formed the communication, as in the preceding part of the experiment; but upon being raised, the scudo was strongly positive, and the balls negative.

But if, previous to the placing of the scudo on the glass, the pith balls be carefully discharged of all adherent electricity, both the upper and lower sides of the glass will be charged with positive electricity, or will give signs of *their being in the same state at the same time.*

It is observable, that the succession of electricities, in the preceding experiments, *seems* to vary according to the priority of contact given to the wire or the scudo. But though this happens most frequently, yet such anomalies take place as not to justify us in considering this singular connexion of diversities as by any means certain.

The appearances I have just described, cannot be shewn on the resinous electrophorus, in consequence of its being fastened to the brass plate ; but, by examining the experiments I have already gone through on this instrument, you will see sufficient reason for admitting that the very same changes would take place if we could introduce the resinous cake into the same circumstances.

Your recurrence to one leading truth, whose evidences, I think, are strengthened by arguing from several of the appearances which I have just now described, will guide you through an easy investigation of the various modes by which all are derived from the

operation of one cause. Remember, that the scudo is never placed upon, or taken off the excited surface, without an attendant diminution or increase of attractive force.

When friction or the Leyden phial has communicated a partial charge to the plate Gh, and when the balls, in contact with its lower side, are consequently separated, the scudo is no sooner in contact with the plate, than the balls instantly close, and when it is taken off, they instantly separate. In perfect consent with the preceding fact, is the diversity which takes place in the charge when the resinous surface is excited with the

scudo *on*, or the scudo *off*. In other words, the introduction of the scudo is that of a new power, amongst whose effects are the singularities which separate the phenomena of the electrophorus from those of the Leyden phial.

CASE I.

The scudo is placed on the positive side of the charged plate. Let us now suppose that when the two bodies are thus joined, an additional force is created, requiring, at the upper surface, a certain quantity of the fluid. This quantity cannot be taken from the accumulation of the charge, though in contact with the scudo; for the whole affinity of the accumulation

is to the attractive force acting on the negative or lower side of the glafs.

The required quantity cannot be taken by forming a connexion with the ground; for before such an addition is made to the upper surface, there must be a contemporaneous removal of an equal quantity from the lower surface.

You hence see the reason why, in the case of the resinous electrophorus, the charge could never be made till a communication was made between the upper surface and the lower surface, and the ground; for, by this means, we not only supply what is wanted, but we at the same time furnish

an opportunity for producing a correspondent deficiency.

We are now to conceive of the apparatus, not only as having the charge communicated by the first excitation, but as having another dependent on the presence of the scudo. Let the scudo be raised, and the whole additional fluid, collected by its attractive power, must be disengaged, and, consequently, a positive spark may be received. The lower side must likewise be negative; for the loss, caused by its first excitation, is now increased. But recollect, that on raising the scudo, and by discharging the positive it caused on the upper side, you leave a negative

on the other side, greater than is answerable to its correspondent accumulation: consequently, the upper side is disposed to receive more, and, though in a different state, shews *exactly the same signs with the lower side.*

CASE II.

When the scudo is placed on the excited surface, let us first touch the wire ab, and then form a connexion with the ground and the upper surface, a quantity of the fluid is immediately disengaged on the upper surface, which goes to answer the additional attractive force caused by the presence of the scudo: the remainder passes off like a common discharge, or it

is disposed of in restoring the equilibrium between the two sides; so that the only charge which remains is that which depends on the operation of the scudo, which, by having touched the wire first, has attracted an accumulation to the lower side: when, consequently, the scudo is raised, or its power destroyed, the lower side is positive, and the scudo negative. But the separation of the scudo leaves the negative, on the upper side, less than what is correspondent to the opposite positive; it is therefore disposed to part with more fluid, and, as in the last case, *shews the same signs of electricity with its correspondent surface.*

I could have shewn you many other varieties of appearances which depend on varying the circumstances of the electrophorus : but I am afraid that a detail, rendered tedious by the endless recurrence of the same words, and by the frequent necessity of provoking the attention to very minute differences, may have excited such strong wishes for the introduction of a new subject, as are altogether unfavourable to the further investigation of the present.

I would, however, observe to you, that the knowledge of what I have been so long describing and explaining, is essential to the character of a good electrician.

When the intricacies of the electrophorus are well considered, few cases can occur, in which the influence of opposite surfaces may not be easily investigated; but when the intricacies of the electrophorus are not understood, we are exposed to the danger of committing endless blunders, and ready to conceive of every new appearance as overturning Dr. Franklin's theory, and as justifying the fabrication of the most absurd conceits and extravagancies.

THE DOUBLER.

This instrument is the invention of Mr. Bennet, to whom we are so much indebted for the electro-

scope, whose advantages we have already so frequently experienced.

By the aid of the doubler, Mr. Bennet designed to ascertain the smallest possible quantity of electricity that can be collected. I will now give you his description of its peculiarities, and of the appearances which result from its operations.

FIG. XXIV.

The doubler consists of two polished plates of glass, A and B, with insulating handles; the handle of one is fixed on the side of the plate, and the other on the centre, where it stands perpendicularly to the surface. The plates are var-

nished on the under sides only.---
When the doubler is to be used,
B is placed on C, a plate communicating with the metallic strips of the electroscope.

The charged surface, which you mean to examine, is brought into contact with B, while resting on C. The finger, or some other body in connexion with the ground, is then brought to touch C, and the plates are immediately afterwards separated, and A is laid on B. A connexion is next formed between A and the ground ; it is afterwards separated from B, and brought into contact with C. While A and C are together, B is again laid on C, and again touched by the finger. The plates are then re-

moved, and the communicated electricity is expressed by the separation of the gold leaf strips in the electroscope.

Each repetition of the process, I have just described, is said to double the quantity of electricity.

The mode of operation is supposed, by Mr. Bennet, to be the following :

By the first application, the lower surface of the varnish of B participates in the electricity of that first charged surface which is brought into contact with it ; an opposite electricity is consequently produced on the upper surface of the varnish of B, or on that which

is nearest the brass plate. When A, therefore, is laid on B, the lower surface of its varnish participates in the electricity of the upper surface of B's varnish, and of course is exactly the same with that of C, and, when added to it, must increase it as often as that addition is made.

The preceding illustration is not, in my opinion, to be reconciled with the acknowledged principles of the Leyden phial. A is laid on B, and, by the simple contact of the finger with the upper surface of its varnish, the lower surface of A becomes charged. This you must perceive, at first sight, to be altogether impossible, unless a communication be at the same time

formed between the lower surface of B and the upper surface of A. It is then analogous to the case of the two Leyden phials, whose opposite sides are connected.

Again, when A is brought near C, with B laid upon it, the charge of its lower surface is supposed to act, not upon its own correspondent upper surface, but upon the upper surface of B, which is consequently supposed to be doubled in its influence by the contemporaneous action of two opposite surfaces: whereas the lower surface of A cannot act at all, unless the charge on its upper surface be at the same time removed: but by doing this, you destroy the very influence which is wanted for the

explanation given by Mr. Bennet ; for the negative, which operates as a doubler, owes its existence to that positive whose removal has taken place.

The idea that the negative of one excited body may be increased, by bringing it close to the positive of another, is altogether erroneous in every instance, but that in which the positive has a contemporaneous opportunity of acting, and even in that instance it takes place only in a certain degree, and in certain circumstances.

1st, If the positive of a charged phial be united with the positive of another phial charged lower than itself, and their negatives be at the

same time connected, then the higher charge will communicate till both are equal. But,

2dly, Though the excited surface in one case be that of immense dimensions, and in the other that of a few inches only, the vast body of electricity in the large surface will communicate no more to the lesser surface, than what is sufficient to bring it into the same state of excitation with itself. This is clear from the following fact.

Experiment. On the two sides of a plate of glass, twelve inches in diameter, I pasted two pieces of tin foil four inches square; when the contents of a battery of thirty square feet, charged as highly as it

could bear, was *gradually* brought near the tin foil on one side, and a connexion took place at the same time between the other sides, the glass plate took the charge only of each distinct phial in the battery, and the diminution of the whole bore the same proportion to the residue, as the surface of the glass plate did to that of the battery.

In the common operations of electricity, you are perpetually witnesses to effects illustrative of the same principle. As soon as the air in the room becomes damp, or any accidental conducting vapour falls on the surface of your working cylinder, however clean your Leyden phials may be, you will

yet find it impossible to charge them; for, let the circumvolutions of your machine be ever so numerous, the phials cannot receive a higher state of excitation than the cylinder which charges them.

You will hence see, that a language which has been lately used with such frequency by electricians, as to become almost habitual, is altogether improper and absurd. They are perpetually talking of condensing the fluid on a particular surface. If they mean any thing by the word *condensation*, they must mean that a quantity, which was previously spread over a large surface, is subsequently confined to a smaller space. In other words, that you may compress

forty particles spread over two square inches, so as to lie on a single square inch. If this be true, then a higher excitation may be caused by a lower, in opposition to all that I have said; for forty particles on an inch square is positive, with a degree of force twice as great as the same particles on two inches square.

Briefly, then, my objections to Mr. Bennett's illustration of the powers of his own doubler are resolved into the following:

1st, He supposes charges to be conveyed from one surface to another, without a proper communication between the surfaces.

2d, He admits, as a principle, the possibility of exciting a greater by an inferior power, or that the negative of B is doubled in the height of its charge by a positive that is exactly of the same height with itself.

3d, He supposes a particular charged surface to operate by its superabundance in producing a negative, previous to the removal of its own correspondent negative.

That the appearances of the doubler are not those of the Leyden phial, will be still more clear, if, instead of the varnished plates, we substitute two very thin glass plates of considerable dimensions, and make them analogous to the

varnished brass, by leaving one side naked, and by coating the other with tin foil. If experiments be thus made on a large scale, the impossibilities I have alluded to become very obvious.

In my opinion, the doubler is a combination of two electrophori. The varnished plate answers to the resinous substance, and the brass plate of the electroscope, with its glass cylinder, is exactly similar to a scudo, insulated by a tube, in the hollow of which are appended two gold leaf strips.

When the varnished plate is placed on the top of the electroscope, the application of a charged phial to its surface operates as an exciter,

and when the varnished plate is raised, the cap of the electroscope, like the scudo when removed from an electrophorus, is charged with the electricity produced from the previous junction of the two bodies.

The varnished plate, B, has its brads now charged with a certain quantity of electricity, or with enough to act as an exciter, when the varnish of A is laid upon it. By the simple application of the finger to A, according to our experiments on the electrophorus, no charge ought to be communicated. A connexion should be formed at the same time with the brads of B: but I have found, that when the resinous substance is laid on

very thinly, and when great care is not taken to keep the metallic surfaces at a proper distance, a spark will be communicated. In the figure given by Mr. Bennet, of his doubler, the piece of brass to which his horizontal handle is fixed, necessarily produces such a connexion.

The spark of A, striking into C, is fully adequate to any increase of electricity that can be communicated to the electroscope.

The appearances which I have endeavoured to explain, are seen on a larger scale by substituting, in the room of the varnished plates, two electrophori, a foot, or a foot

and a half, in dimensions. If the resinous substance be spread over a polished brass plate, the experiments are then in every respect similar, though much less equivocal in their language than those of the doubler.

It is to be observed, however, that whether I am right in my explanation, or otherwise, the doubler, when applied to its intended purpose, may be used with great confidence: it is meant to *collect* a quantity large enough for the decisive examination of that very electricity, which is too feeble in its dispersion to undergo any accurate investigation; and every experiment on the electrophorus proves, that when a charged phial

is brought near enough to strike a spark into the scudo, the electricity of the applied surface will always be the electricity of the scudo.

But it is to be remembered, as a consequence of our experiments on the insulated electrophorus, that appearances would be altogether different, if the varnished plate was not in contact with the brass plate of the electroscope, when the phial is applied.

THE MOVEABLE DOUBLER.

This, like the rest of Mr. Bennet's inventions, is an instrument in its effects very important to the science of electricity.

I prefer Mr. Read's improvement of this instrument for several reasons, but chiefly for the superiority of its insulations.

FIG. XXV.

ABCD gives one view of Read's doubler. The shaded parts of the figure are metal, the unshaded parts glass. A, B, C, are the excited plates, screwed on to the flattened brass at e, f, g: a, is the socket through which the axis passes, by whose means the brass plate revolves.

FIG. XXVI.

Presents another view of the moveable doubler. E is the ter-

mination of the metallic axis. B represents the arm upon which the moveable plate is fixed. A and C are the immoveable plates fixed on their bent insulators. F is a metallic pin, which revolves with the axis, and is connected with M, when the plate B is opposite to A. G is a cross piece of wood or metal, to which a piece of wire, KI, is fastened, so that the whole may participate in the motion of the axis. N is the handle, and is placed so as to counterpoise the weight of the moveable plate. The different wires must be bent, so that when F touches M, there may be no metallic connexion between the immoveable plates; but when IK touches M, then the metallic connexion should be complete be-

tween the plates, or the wire IK should at the same time touch M and H.

The effects of the preceding instrument are the following :

1st, When the handle has been turned eight or ten times round, the plates will be found to have collected a quantity of electricity, sufficiently powerful to be examined by a sensible electroscope. After fifteen or twenty rotations, a spark will strike from one plate to another: but the rapidity of this effect will depend on the care that has been taken to insulate the plates.

2d, The moveable and immove-

able plates may be made either of wood, leather, gypsum, sal ammoniac, sal prunella, allum, glass, or metal, and the nature and the intensity of the electricity will not vary.*

3d, The electricities of the moveable and immoveable plates are always opposite. B is positive when A and C are negative; and B is negative when A and C are positive. But it is not easy to determine, previous to experiment, which plate will be positive, and which negative. This effect depends on a variety of circumstances: according to Mr. Bennet, on the nature of the connexion

* Read on Spontaneous Electricity, p. 29.

formed between the plates and adjoining substances ; and, according to Mr. Read, on the state of the atmosphere in which the doubler is used.

In the experiments of both on this subject, we meet with acknowledged anomalies. Indeed, the experience of such disappointments, and of the embarrassments attending them, is the common fate of those who investigate the changeable electricities of surfaces. This is particularly the case where the expressions of electricity are feeble; nor are we to be surprized, that a small effect should be subject to variation when it is exposed to the influence of the air that is perpetually changing, and of all the

vapours and floating substances which it is perpetually collecting and depositing.

You witnessed the irregularities I allude to, in our experiments on the electrophorus; when, after twenty repetitions succeeding each other, and shewing that its singular appearances depended on the previous contact of the * *upper or lower surface* first, a sudden change took place, and as many subsequent efforts were followed by an uninterrupted series of irregularities.

* Vide p. 172, 173.

FIG. XXVI.

The moveable doubler's mode of operation is, by Mr. Bennet the inventor, supposed to be the following :

He first considers the fluid as existing in C and B; the latter of which plates is necessarily in a state opposite to that of the former.-- When B, thus charged, comes in its rotation opposite to A, the electricity it produces in A is different from its own, and consequently the same with that of C, at the moment in which B a second time is opposed to C. A metallic wire connects C and A, and the power of two negatives acts upon B, and

doubles the intensity of its electricity. By each separate revolution, this doubling process is repeated, so that the accumulation, collected by the successive rotations, is the amount of a geometric series, in which the sum of twelve terms, or the effect of twelve revolutions of the handle, is upwards of a thousand times greater than the first term, or the effect of the first revolution.

If this theory be true, the first production of electricity must be infinitely small ; for, after ten revolutions, the electricity of the best doubler will scarcely affect the most sensible doubler. But, here again, Mr. Bennet has recourse to a principle which I have al-

ready controverted. He assumes the possibility that a negative can act independently of its correspondent positive, and that a negative of one degree of intensity should produce a positive of a higher intensity than that of its own electricity. A, C, and B, are all charged equally high; but A and C together make B higher.

I do not feel the necessity, in the present instance, of introducing a principle which I think, and have endeavoured to prove, is directly opposed by many well known facts.

If the plate of air between B and C be considered as analogous to the varnish between the scudo

and the copper plate, the instrument will then be no more than a common electrophorus, and every previous condition for the charging of the one will be found necessary for the charging of the other.--- Both require the same double communication between their opposite surfaces and the ground, and both have their electricities increased when they are brought near each other, *already charged*. Besides, the opposite electricities of the plates are perfectly analogous to those of the scudo and the copper plate, and it is evident that there must be, with every revolution of the doubler, that increased excitation which is produced by conveying the scudo of one electrophorus charged, to the surface of

another electrophorus uncharged: by this means the electricity of both come to the maximum of their intensity.

When I entered upon Mr. Bennet's explanation of the doubler, I considered the electricity as *already generated*. One question, therefore, still remains to be answered: Whence does that fluid proceed, which, after one revolution, is found in the plates?

Mr. Read maintains that it comes from the surrounding air.—He grounds this hypothesis on the similarity which he always found to take place between the electricity of the doubler, and that of the atmosphere. I cannot reconcile

Mr. Read's opinion with several of Mr. Bennet's experiments, in which he evidently proves that circumstances, whose operation can have no connection with the state of the surrounding atmosphere, change all the appearances produced by the instrument. The whole air of a room cannot surely be affected by so small a difference as that of touching the plate with a piece of lead or a piece of iron. But a total change in the electricities of the plates was found by Mr. Bennet to be the consequence of such a difference. I would not, however, deny that the cause assigned by Mr. Read may not have some effect; for we well know that the nature of communicated electricity materially af-

fects the appearances of the electrophorus.

Mr. Bennet considers "*the approach of the two parallel plates as adequate to the electricity in question.*"

You will remember, that throughout the whole of these Lectures, I have availed myself of this principle, viz. that contact must alter the capacity of bodies, and of course produce a separation of their constituent parts. But however disposed I may be to admit Mr. Bennet's theory as favourable to my own ideas, I am yet inclined to doubt the operation of it, where such a distance separates the two bodies, as that necessary to the operation of the *doubler*. Besides, the motion of the plate through

the air, and the friction of the axis in the collar of the instrument, are very probable sources of excitation.

If the blowing of a little dust from a pair of bellows will produce fluid enough to separate the gold leaf strips, why may not the perpetual percussion of the plate against the air, and the heterogeneous particles with which it is loaded, produce a similar effect?

If marble and metal, by simple contact, excite electricity, why should not the rapid movement of metal in wood, or of metal in metal, be attended with the same consequences?

Do not consider me as asserting that Mr. Bennet is not right ; for I know not at what distance that attractive influence ceases to act, upon whose energy the separation of the fluid depends : but I must feel the preceding objections, till removed by the evidence of experiment.

ON ELECTRICAL LIGHT.

I now proceed to the discussion of certain appearances which are common to all our preceding experiments. From a regard to their varieties and importance, I have reserved them as a separate object of attention. Indeed, I consider the electric fluid and light to be distinct bodies ; and I consequently

thought that you would be more able to comprehend the simple operations of the former, if they were not blended with the effects resulting from its connection with the latter. In the Philosophical Transactions, I have arranged all the peculiarities of electrical light under six general heads. These I shall now repeat to you.

I. There is no fluid or solid body in its passage through which the electric fluid may not be made luminous.

In water, spirits, oil, animal fluid of all kinds, the discharge of a Leyden phial, of almost any size, will appear very splendid, provided we take care to place them in the

circuit, so that the fluid may not pass through too great a quantity of them. My general method is, to place the fluid, on which I mean to make the experiment, in a tube three-fourths of an inch in diameter, and four inches long. I stop up the orifices of the tubes with two corks, through which I push two pointed wires, so that the points may approach within one-eighth of an inch of each other. The fluid, in passing through the interval which separates the wires, is always luminous, if a force be used sufficiently strong. I should observe, that the glass tube always breaks, when this experiment succeeds. To make the passage of the fluid luminous in the acids, they must be placed in capillary

tubes, and two wires inserted as in the preceding experiment, whose points shall be very near each other.

It is a well known fact, that the discharge of a small Leyden phial, in passing a strip of gold, silver, or Dutch metal leaf, will appear very luminous. By conveying the contents of a jar, measuring two gallons, over a strip of gold leaf, one-eighth of an inch in diameter, and a yard long, I have frequently given the whole a dazzling brightness. I cannot say, that a much greater length might not have been made very splendid, nor have I yet determined to what length the contents of a battery might be

made luminous in this manner.---

We may give this experiment a curious diversity, by laying the gold or silver leaf on a piece of glass, and then placing the glass in water; for the whole length of the metallic leaf will appear most brilliantly luminous, by exposing it, thus circumstanced, to the explosion of a battery.

II. *The difficulty of making any quantity of the electrical fluid luminous in any body, increases as the conducting power of that body increases.*

Experiment 1. In order to make the contents of a jar luminous in boiling water, a much higher charge is necessary than would be sufficient to make it luminous in cold

water, which is universally allowed to be the worst conductor.

Exp. 2. I have various reasons for believing the acids to be very good conductors. If, therefore, into a tube filled with water, and circumstanced as I have described, a few drops of either of the mineral acids be poured, it will be almost impossible to make the fluid luminous in its passage through the tube.

Exp. 3. If a string, whose diameter is one-eighth of an inch, and whose length is six or eight inches, be moistened with water, the contents of a jar will pass thro' it luminously; but no such ap-

pearance can be produced by the passage of any charge, provided the same string be moistened with one of the mineral acids.

To the preceding instance we may add the various instances of metals which will conduct the electric fluid without any appearance of light, in circumstances the same with those in which an equal charge would have appeared luminous in passing through other bodies whose conducting power is less.

III. *The ease with which the electric fluid is rendered luminous in any particular body, is increased by increasing the rarity of that body. The appearance of a spark, or of the discharge of a Leyden phial,*

in rarefied air, is well known. But we need not rest the truth of the preceding observation on the several varieties of this fact; similar phænomena attend the rarefaction of æther, of spirits of wine and of water.

Exp. 4. Into the orifice of a tube, forty-eight inches long and two-thirds of an inch in diameter, I cemented an iron ball, so as to bear the weight which pressed upon it when I filled the tube with quicksilver, leaving only an interval at the open end, which contained a few drops of water.— Having inverted the tube, and plunged the open end of it into a basin of mercury, the mercury in the tube stood nearly half an

inch lower than it did in a barometer at the same instant, owing to the vapour which was formed by the water; but through this rarified water the electrical spark passed as luminously as it does thro' air equally rarefied.

Exp. 5. If, instead of water, a few drops of spirits of wine are placed on the surface of the mercury, phænomena, similar to those of the preceding experiment, will be discovered, with this difference only, that as the vapour in this case is more dense, the electrical spark, in its passage through it, is not quite so luminous as it is in the vapour of water.

Exp. 6. Good æther, substituted

in the room of spirits of wine, will press down the mercury so low as the height of sixteen or seventeen inches. The electrical fluid, in passing through this vapour (unless the force be very great indeed) is scarcely luminous: but if the pressure on the surface of the mercury in the bason be gradually lessened by the aid of an air pump, the vapour will become more and more rare, and the electric spark, in passing thro' it, more and more luminous.

Exp. 7. I could not discover that any vapour escaped from the mineral acids, when exposed in vacuo. To give them, therefore, greater rarity or tenuity, I found different methods necessary. With

a fine camel hair pencil, dipped in the vitriolic, the nitrous, or the marine acid, I drew upon a piece of glass a line about one-eighth of an inch broad. In some instances I extended this line to the length of twenty-seven inches, and found that the contents of an electrical battery, consisting of ten pint phials coated, would pass over the whole length of this line with the greatest brilliancy. If, by widening the line, or by laying on a drop of the acid, its quantity was increased in any particular part, the charge, in passing through that part, never appeared luminous. Water or spirits of wine, circumstanced similarly to the acids in the preceding experiment, were attended with similar but not equal effects, be-

cause, in consequence of the inferiority of their conducting power, it was necessary to make the line, through which the charge passed, considerably shorter.

IV. *The brilliancy or splendour of the electric fluid, in its passage through any body, is always increased by lessening the dimensions of that body.* I would explain my meaning by saying, that a spark, or the discharge of a battery, which we might suppose equal to a sphere one-fourth of an inch in diameter, would appear much more brilliant, if the same quantity of the fluid were compressed into a sphere one-eighth of an inch in diameter. This observation is the obvious consequence of many known facts. If

the machine be large enough to afford a spark, whose length is nine or ten inches, this spark may be seen sometimes forming itself into a brush, in which state it occupies more room, but appears very faintly luminous. At other times the same spark may be seen dividing itself into a variety of ramifications, which shoot into the surrounding air. In this case likewise, the fluid is diffused over a large surface, and, in proportion to the extent of that surface, so is the faintness of the appearance. A spark which, in the open air, cannot exceed one-fourth of an inch in diameter, will appear to fill the whole of an exhausted receiver, four inches wide and eight inches long; but in the former case it is brilliant,

and in the latter it grows fainter and fainter, as the size of the receiver increases. To prove the observation, which I think may be justified by the preceding facts, I made the following experiments.

Exp. 8. To an insulated ball, four inches in diameter, I fixed a silver thread about four yards long. — This thread, at the end which was remotest from the ball, was fixed to another insulated substance. I brought the ball within the striking distance of my conductor, and the spark, in passing from the conductor to the ball, appeared very brilliant; but the whole length of the silver thread appeared faintly luminous at the same instant. In other words, when

the spark was confined within the dimensions of a sphere one-eighth of an inch in diameter, it was bright; but when diffused over the surface of air which received it from the thread, its light became so faint, as to be seen only in a dark room. If I lessened the surface of air which received the spark, by shortening the thread, I never failed to increase the brightness of the appearance.

Exp. 9. To prove that the faintness of the electric light in vacuo depends on the enlarged dimensions of the space through which it is diffused, we have nothing more to do, than to introduce two pointed wires into the vacuum, so that the fluid may pass from the

point of the one to the point of the other, when the distance between them was not more than one-tenth of an inch. In this case we shall find a brilliancy as great as in the open air.

Exp. 10. Into a torricellian vacuum, thirty-fix inches in length, I conveyed as much air as would have filled two inches only of the exhausted tube, if it were inverted in water. This quantity of air afforded resistance enough to condense the fluid as it passed through the tube, into a spark thirty-eight inches in length. The brilliancy of the spark in condensed air, in water, and in all substances thro' which it passes with difficulty, depends on principles similar to those

which account for the preceding facts.

V. *In the appearances of electricity, as well as in those of burning bodies, there are cases in which all the rays of light do not escape. The most refrangible are those which escape first or most easily.* The electrical brush is always of a purple or bluish hue. If you convey a spark through a torricellian vacuum, made without boiling the mercury in the tube, the brush will display the indigo rays. The spark, however, may be weakened and divided, even in the open air, so as to yield the most refrangible rays only.

Exp. 11. To an insulated me-

tallic ball, four inches in diameter, I fixed a wire a foot and a half long. This wire terminated in four ramifications, each of which was fixed to a metallic ball half an inch in diameter, and placed at an equal distance from a metallic plate, which communicated by metallic conductors with the ground. A powerful spark, after falling on the large ball at one extremity of the wire, was divided in its passage from the four small balls to the metallic plate. When I examined this division of the fluid in a dark room, I discovered some little ramifications, which yielded the indigo rays only: indeed, at the edge of all weak sparks, the same purple appearance may be discovered. We may likewise ob-

serve, that the nearer we approach the centre of the spark, the greater is the brilliancy of its colour. But I would now wish to shew,

VI. *That the influence of different media on electrical light, is analogous to their influence on solar light, and will help us to account for some very singular appearances.*

Exp. 12. Let a pointed wire, having a metallic ball fixed to one of its extremities, be forced obliquely into a piece of wood, so as to make a small angle with the surface of the wood, and to extend its point one-eighth of an inch below the surface; let another pointed wire, which communicates

with the ground, be forced in the same manner into the same wood, so that its point likewise may be about one-eighth of an inch below the surface, and about two inches distant from the point of the first wire; let the wood be insulated, and a strong spark, which strikes on the metallic ball, will force its passage through that interval of wood which lies between the points, and appears as red as blood. To prove that this appearance depends on the wood's absorption of all the rays, but the red, I would observe that the greater is the depth of the points below the surface, the less mixed are the red rays. I have been able sometimes, by increasing or diminishing the depth of the

points, to give the spark the following succession of colours.

When they were deepest below the surface, the red only came to the eye through a prism. When they were raised a little nearer the surface, the red and orange appeared; when nearer still, the yellow, and so on, till, by making the spark pass through the wood very near its surface, all the rays were at length able to reach the eye. If the points be only one-eighth of an inch below the surface of soft deal wood, the red, the orange, and the yellow rays, will appear as the sparks pass through it: but when the points are at an equal depth in a harder piece of wood (such as box) the

yellow, and perhaps the orange, will disappear.

As a farther proof that the phenomena, I am describing, are owing to the interposition of the wood, as a medium which absorbs some of the rays, and suffers others to escape, it may be observed that when the spark strikes very brilliantly on one side of the piece of deal, on the other side it will appear very red. In like manner, a red appearance may be given to a spark which strikes brilliantly over the inside of a tube, merely by spreading some pitch very thinly over the outside of the same tube.

Exp. 13. I will now give another

fact, whose singularities depend very much on the influence of the medium, through which the electrical light is made to pass. If into a torricellian vacuum, of any length, a few drops of æther are conveyed, and both ends of the vacuum are stopped up with metallic conductors, so that a spark may pass through it, the spark in its passage will assume the following appearances :

When the eye is perfectly close to the tube, the spark will appear perfectly white. If the eye be removed to the distance of two yards, it will appear green; but at the distance of six or seven yards, the colour of the spark will be reddish. These changes evi-

dently depend on the quantity of medium through which the light passes, and the red light more particularly, which we see at the greatest distance from the tube, is accounted for on the same principle as the red light of a distant candle or a beclouded sun.

Exp. 14. Dr. Priestley, long ago, observed the red appearance of the spark, when passing through inflammable air. But this appearance is very much diversified by the quantity of the medium thro' which you look at the spark.—When the eye is at a very considerable distance, the red comes to it unmixed; but if the eye be placed close to the tube, the spark appears white and brilliant. In

confirmation, however, of some of my conclusions, I would observe, that by increasing the quantity of electric fluid which is conveyed through any portion of inflammable air, or by condensing that air, the spark may be entirely deprived of its red appearance, and made perfectly brilliant. I have only to add, that all weak explosions and sparks, when viewed at a certain distance, bear a reddish hue. Such are the explosions which pass thro' water, spirits of wine, or any bad conductor, when confined in a tube, whose diameter is not more than one inch. The reason of these appearances seems to be, that the weaker the spark or explosion is, the less is the light which escapes, and the more visible the

effect of any medium which has a power to absorb some of that light.

The preceding experiments and observations were the consequence of directing my attention to the analogy subsisting between electric light and that of bodies in a state of combustion. In a few queries (expressed at the end of the paper which I have already alluded to) I have conjectured that the same theory may account for both. In the different stages of combustion I have endeavoured to shew that the different rays are emitted in proportion to the degree of decomposition that takes place in the burning body ; that in the nascent state of combustion the violet rays

escape first, then the next in the order of refrangibility succeeds, and so on, till the body at length retains none but the red rays; or that, in their last state of combustion, all bodies must, agreeably to the theory as well as to observation, be of a red colour. On my brief conjectures, as expressed in the Transactions, I will now beg leave to amplify.

1st, I have asked this question, whether the attractive force which unites the constituent parts of different bodies, must not be altered by increasing or diminishing the quantity of any particular constituent which enters into the body? I will thus explain my meaning: suppose the body, D, to be a com-

pound, consisting of three different ingredients, which I call A, B, and C; suppose this compound to retain the union of its parts unaltered, while A consists of fifty particles, B of twenty, and C of ten; while D remains in this undivided state, suppose an exterior force, E, to have an affinity with or to exercise an attractive force upon the particles of the ingredient A, it is evident, from the continued union of D's several parts, that E is not adequate to the separation of those parts, while the quantities of A and B remain unaltered. But let us suppose the reduction of B to ten, it is then obvious that there will be a less force to act upon the ingredients A and B, and that the exterior will then be likely to take

some of those ingredients to itself. Again, let us suppose that A is increased to one hundred, in that case a separation must take place, for the addition will exercise an attractive force upon the particles which are similar to themselves, or upon the fifty particles which already exist in A. The union between A and the two other ingredients will be thus lessened, and consequently the same effects will result from the operation of an exterior influence, as in the preceding instance.

Facts without number seem to shew the actual existence of what I have now stated as undeniable possibilities. All the decompositions produced by adding heat to

such combustibles as are at the time exposed to the influence of the atmosphere, may (in my opinion) be easily accounted for by an application of the last case which I have stated. In like manner, many of the effects of cold may be traced to the causes described in the first of the two cases. As, however, any reasoning derived from the corporeal nature of heat will be rejected by those who ascribe heat to a something unknown, I will state to you some other instances.

Glass is a compound of two bodies, which we call an alkali and an earth. This compound is not at all affected by either of the mineral acids, while the quantity of the

alkali does not exceed one-third of that of the earth, increase the quantity of the alkali to two-thirds, and then unite an acid, and you will find all the alkali immediately separated, and pure silicious earth deposited.

Common sulphur is not operated upon by the air; but if you increase some of the constituent acid, the air immediately prevails, and attaches some of the body to itself. On the Stahlian principles, this instance will apply to the second, but, agreeably to the theory of Lavoisier, it applies to the first of the two cases.

But I proceed to the second question which I asked, and that

is, provided the language I have just now used be admitted, whether the cases I have stated may be applied to the decompositions produced by the electric fluid. Facts without number prove, that when the fluid is added to, or taken away from a body in a certain proportion, a separation of parts in that body is the certain consequence. The charge of a battery will calcine metals, will volatilize oils, will produce air from water, spirits of wine, &c. will break glass, and, in short, produce almost every effect which is caused by other modes of decomposition.

Allowing the truth of what I have now said, we may answer the third question I proposed with.

out difficulty, and we thereby shall come immediately to the elucidation of the fact I would wish to explain.

If light be a constituent part of bodies, and if an addition of the electric fluid causes a separation of parts, must not the addition of it, in a certain degree, be always attended with light? I answer, that several of the general observations I have made, will justify such a conclusion.

- 1st, The addition of the electric fluid, to any body whatever, is attended with a separation of light.
- 2d, The rarer any body is, the easier is the passage of the fluid thro' it made luminous; that is,

agreeably to the theory, the proportion which the addition bears to the constituent parts, is thus considerably increased, and, consequently, the production of the effect is facilitated. — Thus, suppose D to be compounded of $A=10$. and $B=10$. the addition of 100 to the body thus proportioned, would be attended with greater effects than if $A=100$. and $B=100$. A testimony, equal to that of the third observation, is given to my theory by that of the fourth observation, in which I have said, that the brilliancy or splendour of the electric spark, in its passage through any body, is always increased by diminishing the dimensions of the body. My last question, relating to the electric light, was the following:

In the diminution or alteration of that attractive force, on which depends the constitution of bodies, may there be not some gradation which will cause the escape of some rays sooner than others? (i. e.) while a small addition to the constituent electric fluid, in any body, is able to separate from their basis one species of rays, will not a greater addition cause the release of more rays? a greater still, the release of three sorts of rays? and so on, till the addition be adequate to the separation of all the rays, or to the appearance of a brilliant white spark?

The experiments, which I have enumerated, seem to favor strongly this part of the theory, and to

shew, at the same time, that the rays which are first emitted are the indigo, and the spark becomes more and more mixed, as you increase the addition of the fluid, so as to approximate a perfect decomposition. But it is time I should now proceed to another very extensive part of these Lectures, in which, as well as in the preceding, I have no other guide than my own experience, and the conclusions which it has led me to form and to adopt.
